Radiation Therapy Alone. Many series have reported results of external-beam radiation therapy alone. Most include patients with unfavorable features such as clinical T4 disease and multiple positive lymph nodes. For example, in the series of De-Ren,³⁶⁶ 184 of the 678 patients had stage IV disease. Overall, the 5-year survival rate for patients treated with conventional doses of radiation therapy alone is 0% to 10%.^{362,366,367} The use of radiation therapy as a potentially curative modality requires doses of at least 50 Gy at 1.8 to 2.0 Gy per fraction. Shi et al.³⁶⁸ reported a 33% 5-year survival rate with the use of late-course accelerated fractionation to a total dose of 68.4 Gy. However, in the radiation-therapy-alone arm of the RTOG-85-01 trial in which patients received 64 Gy at 2 Gy per day with modern techniques, all patients were dead of their disease by 3 years.^{280,363}

Collectively, these data indicate that radiation therapy alone should be reserved for palliation or for patients who are medically

unable to receive chemotherapy. As is discussed in the following section, the results of chemoradiation are more favorable, and it remains the standard of care.

Definitive Chemoradiation

Conventional Approaches

Comparison of Definitive Chemoradiation and Surgery. There are many single-arm, nonrandomized trials of chemoradiation alone, and they have included patients with disease at a variety of stages.^{355–358} Few series examine patients with T1 or T2 disease.^{369,370} In the series reported by Coia et al.,³⁶⁹ patients received 5-FU and mitomycin C concurrently with 60 Gy of radiation therapy. When results for clinical stage I and II disease are combined, the local failure rate was 25%, the 5-year actuarial local relapse-free survival was 70%, and the 5-year actuarial survival was 30%.

Six randomized trials compared radiation therapy alone with chemoradiation.^{114,263,280,371–375} Of these six trials, five used suboptimal doses of radiation and three used inadequate doses of systemic chemotherapy, and some studies used sequential chemotherapy and radiotherapy rather than concurrent therapy. For example, in the series of Araujo et al.,³⁷⁵ patients received only one cycle of 5-FU, mitomycin C, and bleomycin. The EORTC trial used subcutaneous methotrexate.³⁷¹ In the Scandinavian trial reported by Nygaard et al.,²⁶³ patients received low doses of chemotherapy (cisplatin, 20 mg/m², and bleomycin, 10 mg/m², for a maximum of two cycles). An analysis of pooled data from these trials reported a significant local control and survival benefit at 1 year for chemoradiation compared with radiation therapy alone.³⁷⁶ Chemoradiation was associated with a significant increase in adverse effects, including life-threatening toxicities.

In the ECOG EST-1282 trial,³⁷⁴ patients who received chemoradiation had a significantly increased median survival compared with those who received radiation alone (15 months versus 9 months; $p = 0.04$) but experienced no improvement in 5-year survival (9% versus 7%). However, this was not a pure nonsurgical trial because approximately 50% of patients in each arm underwent surgery after receiving 40 Gy of radiation. Furthermore, this decision depended on the individual investigator's preference. The operative mortality was 17%. Finally, the Pretoria trial reported by Slabber et al.,³⁷³ which was limited to a total of 70 patients with T3 squamous cell cancers, used a low-dose (40 Gy) split-course radiation schedule.

The only trial that was designed to deliver adequate doses of systemic chemotherapy with concurrent radiation therapy was the RTOG-85-01 trial reported by Herskovic et al.,²⁸⁰ and updated by Al-Sarraf et al.³⁷² This Intergroup trial primarily included patients with squamous cell carcinoma. Patients received four cycles of 5-FU (1,000 mg/m² per 24 hour \times 4 days) and cisplatin (75 mg/m² on day 1). Radiation therapy (50 Gy at 2 Gy per day) was given concurrently with day 1 of chemotherapy. Curiously, cycles three and four of chemotherapy were delivered every 3 weeks (weeks 8 and 11) rather than every 4 weeks (weeks 9 and 13). This intensification may explain, in part, why only 50% of the patients finished all four cycles of the chemotherapy. The control arm was given radiation therapy alone, albeit at a higher dose (64 Gy) than the chemoradiation arm.

Patients who received chemoradiation had a significant improvement in median survival (14 months versus 9 months) and 5-year survival (27% versus 0%; $p < 0.0001$).³⁴⁴ There was a clear plateau in the survival curve. Minimum follow-up was 5 years, and the 8-year survival was 22%.^{114,375} The histologic type did not significantly influence the results: 21% of patients with squamous cell carcinomas ($n = 107$) were alive at 5 years compared with 13% of patients with adenocarcinoma ($n = 23$) (p was not significant). Although African Americans had larger primary tumors, all of which were squamous cell cancers, there was no difference in their survival compared with that of Caucasians.³⁷⁷ The incidence of local

failure as the first site of failure (defined as local persistence or recurrence) was also decreased in the chemoradiation arm (47% versus 65%). The protocol was closed early because of the positive results; however, after this early closure, an additional 69 eligible patients were treated with the same chemoradiation regimen. In this nonrandomized combined modality group, the 5-year survival was 14% and local failure was 52%.

Chemoradiation not only improves the results compared with radiation alone but also is associated with a higher incidence of toxicity. In the 1997 report of the RTOG-85-01 trial, patients who received chemoradiation had a higher incidence of acute grade 3 toxicity (44% versus 25%) and acute grade 4 toxicity (20% versus 3%) compared with those who received radiation therapy alone. Including the one treatment-related death (2%), the incidence of total acute grade 3+ toxicity was 66%.³⁷² The 1999 report examined late toxicity. The incidence of late grade 3+ toxicity was similar in the chemoradiation arm and in the radiation-alone arm (29% versus 23%).¹¹⁴ However, grade 4+ toxicity remained higher in the combined modality arm (10% versus 2%). Interestingly, the nonrandomized chemoradiation group experienced a similar incidence of late grade 3+ toxicity (28%) but a lower incidence of grade 4 toxicity (4%), and there were no treatment-related deaths.

Based on the positive results from the RTOG-85-01 trial, the conventional nonsurgical treatment for esophageal carcinoma is chemoradiation. Notwithstanding, the local failure rate in the RTOG-85-01 chemoradiation arm was 45%, and there is room for improvement. Therefore, new approaches, such as intensification of chemoradiation and escalation of the radiation dose, have been developed in an attempt to help improve these results.

Randomized Trials. Although there are a number of trials comparing preoperative chemoradiation with surgery alone, there are only two trials that directly compare nonoperative treatment with surgery. One randomized trial compared surgery with radiation alone³⁷⁸ and one compared surgery with chemoradiation.³⁷⁹ Both series have small numbers of patients, limited follow-up, and neither report a difference in survival.

Nonrandomized Trials. The positive results of RTOG-85-01, demonstrating a 27% 5-year survival rate for patients treated with definitive chemoradiation compared with no 5-year survival after treatment with radiotherapy alone, is a major advance. This treatment option has influenced the selection of patients for nonsurgical management because it provides an alternative for restoring swallowing function in patients with locally advanced disease for whom resection would likely be palliative.

For patients with earlier-stage disease that appears resectable, definitive chemoradiation may also be appropriate treatment; however, prospective trials comparing this approach with surgery, stratified by stage, have not been performed. Nonetheless, nonrandomized comparisons of contemporary series suggest that the nonsurgical approach offers a survival rate that is the same or better than that achievable with surgery alone. For example, the median survival time and 5-year survival rate were 14 months and 27%, respectively, in the chemoradiation arm of RTOG-85-01, and 20 months and 20%, respectively, in INT-0122.³⁸⁰ In comparison, the median survival in the surgical control arm of the Dutch trial reported by Kok et al.²⁶⁹ was 11 months, and the median survival time and 5-year survival rate in the surgical control arm of INT-0113 were 16 months and 20%, respectively. Likewise, the local failure rates were similar. The incidence of local failure (local recurrence plus local persistence of disease) as the first site of failure was 45% in RTOG-85-01 and 39% in INT-0122. If all patients, including patients failing to undergo surgery or patients having an R2 resection are included, the local failure as the first site of failure was 61% on the surgical trial INT-0113, which is actually higher than the 45% reported on RTOG-85-01. The treatment-related mortality rates were also similar (2% in RTOG-85-01, 9% in INT-0122, and 6% in INT-0113).

In summary, the local failure, survival, and treatment-related mortality rates for nonsurgical and surgical therapies are similar. Although the results are comparable, it is clear that both the nonsurgical and surgical approaches have limited success.

Necessity for Surgery After Chemoradiation. Two randomized trials examine whether surgery is necessary after chemoradiation. In the Fédération Française de Cancérologie Digestive (FFCD) 9102 trial, 444 patients with clinically resectable T3-4N0-1M0 squamous cell or adenocarcinoma of the esophagus received initial chemoradiation.¹¹⁶ Patients initially received two cycles of 5-FU, cisplatin, and concurrent radiation (either 46 Gy at 2 Gy per day or split course 15 Gy weeks 1 and 3). The 259 patients who had at least a partial response were then randomized to surgery versus additional chemoradiation, which included three cycles of 5-FU, cisplatin, and concurrent radiation (either 20 Gy at 2 Gy per day or split course 15 Gy). Two-year local control was 66% in the surgery arm versus 57% in the chemoradiation-alone arm. There was no significant difference in 2-year survival (34% versus 40%; $p = 0.44$) or median survival (17.7 months versus 19.3 months) in patients who underwent surgery versus additional chemoradiation. These data suggest that patients who initially respond to chemoradiation should complete chemoradiation rather than stop and undergo surgery. Using the Spitzer index, there was no difference in global quality of life; however, a significantly greater decrease in quality of life was observed in the surgery arm during the postoperative period (7.52 versus 8.45; $p < 0.01$, respectively).³⁸¹ A separate analysis revealed that compared with split course radiation, patients who received standard course radiation had improved 2-year local relapse-free survival rates (77% versus 57%; $p = 0.002$) but no significant difference in overall survival (37% versus 31%).³⁸²

The German Oesophageal Cancer Study Group compared preoperative chemoradiation followed by surgery versus chemoradiation alone.¹¹⁷ In this trial, 172 eligible patients age 70 years or more with uT3-4N0-1M0 squamous cell cancers of the esophagus were randomized to preoperative therapy (three cycles of 5-FU, leucovorin, etoposide, and cisplatin, followed by concurrent etoposide, cisplatin, plus 40 Gy) followed by surgery versus chemoradiation alone (the same chemotherapy but the radiation dose was increased to 60 to 65 Gy with or without brachytherapy). The pathologic complete response (pCR) rate was 33%. Despite a decrease in 2-year local failure (36% versus 58%; $p = 0.003$), there was no significant difference in 3-year survival (31% versus 24%) for those who were randomized to preoperative chemoradiation followed by surgery versus chemoradiation alone.

The current standard of care is to perform esophagectomy following chemoradiation in patients that can tolerate this approach. However, it is known that a subset of patients will have a complete response to chemoradiation. Further, patients with pCR have improved survival. Data from both Berger et al.³⁸³ and Rohatgi et al.³⁸⁴ suggest that patients who achieve a pCR had an improvement in survival compared to those who do not (5-year: 48% versus 15%, and median: 133 months versus 34 months, respectively). In these patients, surgical resection may not be necessary and has led to the concept of *selective* surgery after preoperative chemoradiation.

Swisher et al.³⁸⁵ reported a retrospective analysis of patients who underwent a salvage compared with a planned esophagectomy at the M.D. Anderson Cancer Center from 1987 to 2000. The operative mortality was higher in those who underwent salvage versus planned surgery (15% versus 6%), but there was no difference in survival (25%). Because only 13 patients were identified who had salvage, the results need to be interpreted with caution. This approach formed the basis of a phase II Radiation Therapy Oncology Group (RTOG) trial (RTOG 0246), which prospectively examined the approach of preoperative paclitaxel/CDDP and 50.4 Gy followed by selective surgery in patients with either residual disease or recurrent disease in the absence of distant metastasis. In this trial of 43 patients with locally advanced disease, 21 patients required surgical resection after chemoradiation due to residual

(17 patients) or recurrent (3 patients) disease and one patient by choice.³⁸⁶ This approach led to a 1-year overall survival of 71% and was closed early because it did not meet the predetermined survival rate of 78%.

Tumor Markers and Predictors of Response to Chemoradiation. It would be helpful to predict which tumors have a higher likelihood of responding to radiation or chemoradiation. Geh et al.³¹⁶ performed a systematic review to identify factors associated with a higher rate of pCR in patients receiving preoperative chemoradiation. The analysis was limited to the 26 trials meeting four criteria: (1) at least 20 patients treated, (2) a single chemoradiation regimen was delivered, (3) 5-FU, cisplatin, or mitomycin C–based chemotherapy was used, and (4) there was information on patient numbers, age, resection, and pCR rates. Overall, the pCR rate was 24% and the probability of pCR increased with increasing radiation dose ($p = 0.006$) and the use of a 5-FU-based ($p = 0.003$) or cisplatin-based ($p = 0.018$) regimen. In contrast, increased radiation treatment time ($p = 0.035$) and median age ($p = 0.019$) both decreased the chance of a pCR.

Data from both Berger et al.³⁸³ and Rohatgi et al.³⁸⁴ suggest that patients who achieve a pCR had an improvement in survival compared with those who do not (5-year, 48% versus 15%, and median, 133 months versus 34 months, respectively). However, the ability to predict a pCR prior to surgery is variable, as discussed earlier. A multivariate analysis by Gaca et al.³⁸⁷ reported that posttreatment nodal status ($p = 0.03$), but not the degree of primary tumor response, predicted disease-free survival. Studies have linked tumor lymphocytic infiltration as well as the apoptotic index with response to chemoradiation.³⁸⁸ Additional studies have linked a large number of proteins and genes involved in a wide array of signaling cascades with response to chemoradiation. Examples include alterations in diverse signaling cascades involving PI3 kinase, p53, EGFR, and hypoxia-inducible factor 1 alpha (HIF-1a).^{389–394} Unfortunately, the vast majority of these studies lack validation and the specificity required to be used clinically. One recent study generated a micro-RNA signature to predict pCR from tumors in 52 patients treated uniformly with chemoradiation.³⁹⁵ This signature was then validated in a separate cohort of 72 patients treated similarly. When combined with clinical stage, the area under the curve (AUC) for pathologic complete response (pCR) was 0.77 ($p = 2 \times 10^{-41}$).

Posttreatment imaging does not consistently identify the response. An ultrasound following chemoradiation does not accurately predict a pCR.³⁹⁶ In contrast, Blackstock et al.³⁹⁷ reported that the percentage of decrease in standard uptake value measured by 18F-FDG-PET predicted response, and Brucher et al.³⁹⁸ found that it correlated with survival. McLoughlin et al.³⁹⁹ treated 81 patients with preoperative chemoradiation and reported that FDG-PET scans were able to predict a pathologic complete response with 62% sensitivity, 44% specificity, and 56% accuracy.

The predictive ability of molecular markers has been examined. In 38 patients with squamous cell carcinoma who received chemoradiation with or without surgery, tumors without p53 expression and tumors with weak Bcl-X_L expression showed a higher response to chemotherapy (56% and 53%, respectively) than tumors positive for p53 or with strong Bcl-X_L expression (30% and 32%, respectively; p not significant).⁴⁰⁰ After preoperative chemoradiation, patients with p53-negative tumors had a significantly better mean survival than those with p53-positive tumors (31 months versus 11 months; $p = 0.0378$). By multivariate analysis, Pomp et al.⁴⁰¹ found that overexpression of p53 resulted in a decrease in the survival in 69 patients with squamous cell carcinoma or adenocarcinoma treated with radiation alone. In one study, there was a correlation between decreasing levels of four phospholipids and increasing T stage and grade.⁴⁰²

Understanding the mechanism of radioresistance through the identification and targeting of molecular pathways by serum protein profiling⁴⁰³ and the identification of genes involved in apoptosis,⁴⁰⁴ activated transcription factor nuclear factor κB (NF-κB),³⁹²

and microvascular density⁴⁰⁵ may offer new opportunities for therapeutic advances.

Intensification of Chemoradiation. The phase II Intergroup trial 0122 (ECOG-PE289/RTOG-90-12) was designed to intensify treatment in the RTOG-85-01 combined modality arm.³⁸¹ Both the chemotherapy and radiation therapy in INT-0122 were intensified by 20%.⁴⁰⁶ The median survival time was 20 months and the 5-year actuarial survival rate was 20%. Similar toxicities were reported by Ishikura et al.⁴⁰⁷ for 139 patients with squamous cell cancers treated with 5-FU, cisplatin, and 60 Gy of radiation. However, the higher radiation dose (64.8 Gy) in INT-0122 was tolerated and compared with the 50.4 Gy of radiation in the Intergroup trial INT-0123, discussed as follows.

A potential advantage of neoadjuvant chemotherapy is the early identification of those patients who may or may not respond to the chemotherapeutic regimen being delivered concurrently with chemoradiation. Ilson et al.¹⁰¹ have shown that the change in standard uptake value (SUV) on FDG-PET scan was able to predict which patients showed a response to the full course of chemotherapy followed by chemoradiotherapy. Weider and associates⁴⁰⁸ reported similar findings in 38 patients with squamous cell cancers. As discussed previously, the use of an early PET scan during induction chemotherapy to direct subsequent chemotherapy during combined chemoradiotherapy is the subject of an ongoing Alliance Trial.

Amini et al.⁴⁰⁹ performed a retrospective review of 141 patients who achieved an initial clinical complete response (cCR) after chemoradiation. By a multivariate analysis, the initial SUV of >10 and poorly differentiated tumors had a significantly higher incidence of in-field failure.⁴⁰⁹

Intensification of the Radiation Dose. Another approach to the dose intensification of chemoradiation is increasing the radiation dose above 50.4 Gy. There are two methods by which to increase the radiation dose to the esophagus: brachytherapy and external-beam radiation therapy.

Brachytherapy. Intraluminal brachytherapy allows for the escalation of the dose to the primary tumor while protecting the surrounding dose-limiting structures such as the lung, heart, and spinal cord.⁴¹⁰ A radioactive source is placed intraluminally via bronchoscopy or a nasogastric tube. Brachytherapy has been used both as primary therapy (usually palliative)^{411,412} and as a boost after external-beam radiation therapy or chemoradiation.^{413–415} It can be delivered by high-dose rate or low-dose rate.⁴¹⁶ Although there are technical and radiobiologic differences between the two dose rates, there are no clear therapeutic advantages for either.

Series that combine brachytherapy with external-beam radiation therapy or chemoradiation report results similar to those for conventional chemoradiation. Yorozu et al.⁴¹⁵ reported a local failure rate of 57% and a 5-year actuarial survival of 28% in 46 patients with stage T2-3N0-1M0 disease. Even for a more favorable subset of patients with clinical T1 to T2 disease, Yorozu et al.⁴¹⁷ reported a local failure rate of 44% and a 5-year survival of 26%. In the series by Pasquier et al.,⁴¹⁴ local failure was 23% and 5-year survival was 36%. In an updated series by Ishikawa et al.,⁴¹⁸ 59 patients with submucosal esophageal cancer received external-beam therapy followed by brachytherapy in 36 patients with either low-dose rate caesium-137 (¹³⁷Cs) (17 patients) or high-dose rate iridium-192 (¹⁹²Ir) (19 patients). Patients selected to receive a brachytherapy boost had a significantly higher 5-year cause specific survival (86% versus 62%; $p = 0.04$).

In the RTOG-92-07 trial, 75 patients with squamous cell cancers (92%) or adenocarcinomas (8%) of the thoracic esophagus received the RTOG-85-01 combined modality regimen (5-FU, cisplatin, and 50 Gy of radiation) followed by a boost during cycle three of chemotherapy with either low-dose rate or high-dose rate intraluminal brachytherapy.⁴¹⁹ Because of low accrual, the low-dose rate option was discontinued and the analysis was limited

to patients who received the high-dose rate treatment. High-dose rate brachytherapy was delivered in weekly fractions of 5 Gy during weeks 8, 9, and 10. After the development of several fistulas, the fraction delivered at week 10 was discontinued. Although the complete-response rate was 73%, the rate of local failure was 27%. Rates of acute toxicity were 58% for grade 3, 26% for grade 4, and 8% for grade 5 (treatment-related death). The cumulative incidence of fistula was 18% per year and the crude incidence was 14%. Of the six treatment-related fistulas, three were fatal. Given the significant toxicity, this treatment approach should be used with caution.⁴²⁰ Based on these and other data, the American Brachytherapy Society has developed guidelines for esophageal brachytherapy.⁴²¹⁻⁴²³

External-Beam Therapy: 2D and 3D Techniques. Because almost all patients in both the INT-0122 trial who started radiation therapy were able to complete the full dose (64.8 Gy), this higher dose of radiation was used in the experimental arm of the Intergroup esophageal trial INT-0123 (RTOG-94-05).²⁸¹ In this trial, patients with either squamous cell carcinoma or adenocarcinoma who were selected for nonsurgical treatment were randomly assigned to receive a slightly modified RTOG-85-01 combined modality regimen with 50.4 Gy of radiation versus the same chemotherapy with 64.8 Gy of radiation.

The modifications to the original RTOG-85-01 chemoradiation arm includes (1) using 1.8-Gy fractions to 50.4 Gy rather than 2-Gy fractions to 50 Gy; (2) treating with 5-cm proximal and distal margins for 50.4 Gy rather than treating the whole esophagus for the first 30 Gy followed by a cone down with 5-cm margins to 50 Gy; (3) cycle three of 5-FU and cisplatin did not begin until 4 weeks after the completion of radiation therapy rather than 3 weeks after; and (4) cycles three and four of chemotherapy were delivered every 4 weeks rather than every 3 weeks.

INT-0123 was closed to accrual in 1999 with 218 patients after an interim analysis revealed that it was unlikely that the high-dose arm would achieve superior survival compared with the standard-dose arm: There was no significant difference in median survival time (13.0 months versus 18.1 months) or 2-year survival rate (31% versus 40%) between the high-dose and standard-dose arms.²⁸¹ Although 11 treatment-related deaths occurred in the high-dose arm compared with 2 in the standard-dose arm, 7 of the 11 deaths occurred in patients who had received 50.4 Gy or less.

Although the crude incidence of local failure or persistence of local disease (or both) was lower in the high-dose arm than in the standard-dose arm (50% versus 55%), as was the incidence of distant failure (9% versus 16%), these were not significant. Although retrospective data from the M.D. Anderson Cancer Center suggest a positive correlation between radiation dose and local-regional control,⁴²² the results of the INT-0123 trial maintain the standard dose of 50.4 Gy.

The modifications to the original RTOG-85-01 chemoradiation arm outlined earlier did not adversely affect the local control or survival rate in the control arm of INT-0123. Therefore, the radiation doses and field design used in the control arm of INT-0123 should be used.

Radiation can be intensified not only by increasing the total dose, but also by using accelerated fractionation or hyperfractionation. This approach has revealed modest results. Zaho and colleagues⁴²⁴ treated 201 patients with squamous cell cancer using 41.4 Gy followed by late-course accelerated hyperfractionation to 68.4 Gy. The results were similar to RTOG 85-01 (38% local failure and 26% 5-year survival). Choi and colleagues⁴²⁵ treated 46 patients with 5-FU/cisplatin and twice per day radiation using a concurrent boost technique and reported a 37% 5-year survival. Additionally, Lee et al.³⁴⁵ reported on a trial of 102 patients with locally advanced disease, limited to squamous cell carcinoma, randomized to surgery alone versus preoperative therapy with 45.6 Gy (1.2 Gy twice per day) plus 5-FU/cisplatin. There was no difference in median survival (28 versus 27 months). Thus, although

these approaches appear to be reasonable, there appears to be a significant increase in acute toxicity without any clear therapeutic benefit.

Dose Escalation: Intensity Modulated Radiation Therapy and Protons. A criticism of many dose escalation trials in the definitive management of locally advanced esophageal cancer is the use of conventional two-dimensional (2D) and three-dimensional (3D) radiation techniques. Trials using newer techniques such as intensity-modulated radiation therapy (IMRT) and protons may be able to deliver higher doses of radiation with a more tolerable toxicity profile. Multiple dosimetric studies comparing standard 3D-conformal radiotherapy and IMRT, generally have found improved sparing of the heart, lung, or both using either static field or arc-based IMRT.⁴²⁶⁻⁴³⁵ This has led multiple clinical centers to begin the routine use of IMRT in this disease. A retrospective analysis of these data does not suggest an inferior outcome and may provide decreased toxicity versus non-IMRT treatment techniques.⁴³⁶⁻⁴³⁸ Investigators at the M.D. Anderson Cancer Center reported the results of 676 patients with locally advanced disease treated with either IMRT (263 patients) or 3D conformal radiation therapy (3DCRT) (413 patients).⁴³⁶ On a multivariate analysis, IMRT was associated with improved survival ($p = 0.004$), but not cancer-specific survival ($p = 0.86$). The survival difference between 3DCRT and IMRT was thought to be due to a higher level of cardiac deaths ($p = 0.05$) and unexplained deaths ($p = 0.003$) in the 3DCRT patients, suggesting that decreased cardiac dose may have a direct impact on patient outcome. Although this and other comparisons between 3DCRT and IMRT are retrospective, a randomized trial is unlikely, thus the available data may represent the best comparison.

Another theoretical advantage of IMRT is the possibility of dose escalation. With the use of IMRT, a simultaneous integrated boost (SIB) may be performed while maintaining commonly used lung and heart dosimetric constraints. Retrospective data from Zhang and colleagues⁴²² suggest a positive correlation between radiation dose and local-regional control. This has led to a phase I study examining this approach in locally advanced disease. However, at this point, based on results of the INT-0123 trial, the standard dose of external beam radiation remains 50.4 Gy.

New Chemoradiation Regimens. Because 75% to 80% of patients die of metastatic disease, advances in systemic therapies are necessary for a further improvement of results. The most widely used chemotherapeutic regimen to be combined with radiation for the treatment of esophageal cancer is 5-FU and cisplatin. A number of new cytotoxic and targeted regimens are being evaluated in both the preoperative and nonoperative setting. These are discussed previously in the section on preoperative chemoradiation regimens.

Palliation of Esophageal Cancer with Radiation Therapy

Palliation of Dysphagia and Bleeding. Many of the series examining dysphagia are retrospective, and most do not use objective criteria to define and assess dysphagia. Some do not report the number of patients presenting with dysphagia or the percentage who receive palliative treatment until the time of death. Furthermore, few series carefully examine other variables that may influence the results, such as histologic type, stage, and location of the primary tumor.

Options for palliation include stents, feeding tubes, chemotherapy, and external-beam radiation therapy or brachytherapy (or both). The selection of the technique is variable and commonly is based on physician preference. In a randomized trial from the Dutch SIREC Study Group of stent versus one 12-Gy fraction of brachytherapy, dysphagia, as measured by a variety of quality-of-life scales, improved more rapidly after stent placement; however, long-term relief was

superior after brachytherapy.⁴¹² Median survivals were similar (145 days versus 155 days).

Patients for whom stents fail are commonly treated with palliative radiation. Li et al.⁴³⁹ reported that the presence of a metal stent increases the radiation dose 5% to 10% at a 0.5-cm depth in the esophageal wall. Therefore, the radiation dose should be decreased by 5% to 10% when a metal stent is in the radiation field. Nishimura et al.⁴⁴⁰ reported a high-grade 3+ complication rate in 47 patients who underwent stent placement before or during radiation treatment and recommend that stent placement be delayed until radiation therapy has failed.

As seen in Table 45.8, series have examined the palliative benefits of either radiation alone^{371,441-444} or chemoradiation.^{406,443,445-450} Overall, external-beam radiation therapy alone provides palliation of dysphagia in 70% to 80% of patients.

The most comprehensive and carefully performed analysis of swallowing function in patients receiving chemoradiation is by Coia et al.⁴⁵⁰ Using a swallowing score modified from O'Rourke et al.,⁴⁵¹ they analyzed 102 patients treated with three 5-FU-based combined modality regimens. Before the start of therapy, 95% of patients had some degree of dysphagia. Within 2 weeks after the start of treatment, 45% had improvement in dysphagia, and by the completion of the 6-week therapy, 83% had improvement. Overall, 88% experienced an improvement in dysphagia. The median time to improvement was 4 weeks (range, 1 to 21 weeks), and all but two patients could swallow at least soft or solid foods. Harvey et al.⁴⁴⁶ treated 106 patients and reported that 78% had improvement of at least one grade in their dysphagia score; 51% maintained swallowing improvement until the time of last follow-up.

Intraluminal brachytherapy is also an effective, albeit a more limited method, achieving palliation of dysphagia in 35% to 80% of patients and a median survival of 5 months. A major limitation of brachytherapy is the effective treatment distance. The primary isotope is ¹⁹²Ir, which is usually prescribed to treat to a distance of 1 cm from the source. Any portion of the tumor that is more than

1 cm from the source will receive a suboptimal radiation dose, confirmed by pathologic analysis of surgical specimens.⁴⁵² Given its limited effective range, brachytherapy is usually not as successful as external-beam radiation therapy in treating the entire tumor volume. However, in a randomized trial, there was no difference in local control or survival with high-dose-rate brachytherapy as opposed to external-beam radiation therapy.⁴⁵²

If a patient requires rapid palliation (within a few days), alternative approaches such as laser treatment or stent placement are recommended. Although external-beam radiation with or without chemotherapy takes at least 2 weeks to produce palliation, once palliation is achieved it is more durable than that provided by the other palliative modalities because external-beam radiation treats the problem (the gross tumor mass), not just the symptom. If external-beam radiation is not possible, then intraluminal brachytherapy should be considered because it is an effective modality for decreasing symptoms such as dysphagia and bleeding. Chemotherapy by itself may also substantially relieve dysphagia when used as an initial treatment of metastatic disease.

Treatment in the Setting of Tracheoesophageal Fistula

The presence of a malignant tracheoesophageal fistula usually results in poor survival, although occasionally, patients may survive for a prolonged period. Historically, radiation therapy was believed to be contraindicated for these patients for fear of exacerbating the fistula as the tumor responded. More recently, there have been reports to the contrary. In a Mayo Clinic series, 10 patients with malignant tracheoesophageal fistulas received 30 to 66 Gy external-beam radiation, and the median survival time was 5 months.⁴⁵³ A series from Japan that treated 24 patients with fistulization to the airway reported ultimate closure of the fistula after chemoradiotherapy in 17 patients, with time to closure ranging from 6 to 280 days.⁴⁵⁴

TABLE 45.8

Palliation of Dysphagia with Radiation Therapy with or without Chemotherapy

Study (Ref.)	No. of Patients	Palliation of Dysphagia ^a	
		At the End of Treatment (%)	Duration
Raditation Therapy Alone

^a See text for definition and number of patients presenting with dysphagia.

^b Patients had dilation or neodymium yttrium-aluminum garnet laser treatment at the start of therapy.

Although the experience is very limited, the data suggest that radiation treatment does not necessarily increase the severity of a malignant tracheoesophageal fistula and it can be administered safely. It is unclear if radiation treatment improves outcome.

Acute and Long-Term Toxicity of Radiation Therapy. The toxicity of radiation therapy is a function of what the total dose is, what technique is used, and whether the patient has received chemotherapy. Essentially all patients experience lethargy and esophagitis commencing 2 to 3 weeks after the start of radiation therapy; these symptoms usually resolve 1 to 2 weeks after completion of therapy.

The most carefully documented acute toxicity data for patients who receive radiation therapy alone (without chemotherapy) are from the control arm of RTOG-85-01 in which patients received radiation therapy alone to a dose of 64 Gy.^{280,372} The incidence of acute grade 3 toxicity was 25% and the incidence of acute grade 4 toxicity was 3%. The incidence of long-term grade 3+ toxicity and long-term grade 4+ toxicity was 23% and 2%, respectively. Radiation therapy can produce esophageal strictures, as can surgery. The total incidence of stricture (benign plus malignant) in patients receiving radiation therapy alone or radiation combined with chemotherapy is 20% to 40% in a modern series and up to 60% in historical series,⁴⁵³ with up to 50% malignant, associated with recurrence. The incidence of stricture is lower in series in which careful radiation techniques were used. Coia et al.⁴⁵⁰ examined a subset of 25 patients who experienced local control and survived at least 1 year. The incidence of benign stricture was 12%. Radiation toxicity is related to dose–volume effects.⁴⁵⁶

One series examined the functional outcomes of benign and malignant strictures.⁴⁵¹ Patients received 45 to 56 Gy and 53% received some form of chemotherapy. Of the 24 patients (30%) who developed a benign stricture, 71% were able to tolerate a full or soft diet and required dilation, with a median interval between dilations of 5 months. Even in the subset of patients who develop a benign stricture, dilation is effective in the majority of patients. In contrast, in the 28% of patients who developed a malignant stricture, dilation was unsuccessful and esophageal intubation was required.

The high incidence of fistula reported in the RTOG-92-07 trial of chemoradiation plus intraluminal brachytherapy (18% actuarial, 14% crude) has not been seen in series using radiation therapy or chemoradiation. The incidence of other long-term grade 3+ toxicities such as pneumonitis or pericarditis is 5%.

The effect of radiation on pulmonary function was examined by Gergel et al.⁴⁵⁷ Patients received 39.6 Gy with anterior–posterior fields followed by radiation with oblique fields to a total dose of 50.4 Gy, plus concurrent chemotherapy with oxaliplatin and 5-FU. Results of pulmonary function tests administered before and a median of 16 days after radiation revealed significant declines in diffusing capacity for carbon monoxide and total lung capacity. Investigators at the M.D. Anderson Cancer Center performed retrospective treatment-planning studies on 10 patients and found that IMRT reduced the dose volume of exposed normal lung but had no clinically meaningful differences on the irradiated volumes of spinal cord, heart, liver, or total body integral doses.⁴²⁶ The impact of respiratory and organ movement on defining target volumes is being investigated.^{458,459}

The issue of treatment-related deaths in patients who receive chemoradiation is complex. Although the incidence was only 2% in RTOG-85-01, subsequent trials have reported a higher treatment-related mortality rate (i.e., 9% in INT-0122 and 8% in RTOG-92-07). These mortality rates are lower than the 10% to 15% incidence reported in historical surgical series, although only slightly higher than the 6% reported in the surgical control arm of INT-0113.¹⁰⁵ It is interesting to note that, as the mortality rate with surgery has decreased, there has been a corresponding increase in the treatment-related mortality rate reported in the nonoperative trials. As previously discussed in Primary Nonsurgical Therapy,

this may be partly related to bias in selecting patients to be treated with the nonoperative approach.

Radiation Field Design and Treatment Techniques. Just as expert surgical skills are required for a successful esophagectomy, radiation field design for esophageal cancer requires careful planning. Historically, the standard radiation dose, based on INT-0123, for patients selected for chemoradiation is 50.4 Gy at 1.8 Gy per fraction. However, recent data from the CROSS trial suggest that 41.4 Gy in the same fractionation may be sufficient to treat in the preoperative setting. As previously described, some investigators have performed dose escalation; however, based on INT-0113, dose escalation above 50.4 Gy should not be performed off protocol. Additionally, radiation should be delivered without treatment breaks, as randomized data from France reveal a higher local control (57% versus 29%) and 2-year survival rate (37% versus 23%) with continuous course compared with split course radiation.³⁸²

The radiation field should include the primary tumor with 5 cm superior and inferior margins and 2 cm lateral margins. The primary local–regional lymph nodes should receive the same dose. For cervical (proximal) primary tumors (defined as at or proximal to the carina), the treatment volume includes the bilateral supraclavicular nodes, and for GEJ (distal) primaries, the celiac axis nodes should be included.

Treatment Modality. At many centers, the standard of care in radiotherapy for locally advanced esophageal cancer is 3D conformal radiotherapy using a beam arrangement optimized via CT scan–based planning. However, as mentioned previously, many clinicians have used IMRT with a possible benefit with regard to toxicity and no apparent compromise in oncologic outcome.⁴³⁶ A comparison of three techniques is shown in Figure 45.14. If IMRT is to be used, careful attention should be given to target delineation. In addition, particularly in the case of distal/GEJ tumors, 4D CT or other forms of motion management should be considered.

Recently, proton radiotherapy has become more available as a treatment modality. By virtue of its physical characteristics, proton radiotherapy is thought to decrease dose to critical structures, in large part by minimizing the low-dose “bath” often seen with IMRT. This is to some degree shown in dosimetric studies, with V5, V10, and V20 to the lung and heart with protons compared to IMRT (see Fig. 45.14). Several studies have examined patient outcome after treating with proton radiotherapy. Sugahara and colleagues⁴⁶⁰ examined outcomes in 46 patients with squamous cell carcinoma treated with protons with or without photons to a median total dose of 76 Gy.⁴⁶⁰ The 5-year local control rate was for T1: 83%, for T2 through 4: 29%, and for survival T1: 55% and for T2 through 4: 13%. Koyama⁴⁶¹ reported mean actuarial survival rates of 60% for patients with superficial and 39% for those with advanced disease treated to mean total doses of 78 to 81 Gy. The incidence of esophageal ulcer was 67%. In the United States, Lin and colleagues⁴⁶² retrospectively reviewed 62 patients treated with proton radiotherapy for locally advanced disease. Overall, 47% were treated with surgical resection following chemoradiation, with a pCR rate in these patients of 28%. In this series, two patients (3.2%) developed symptomatic pneumonitis and an additional two patients died due to treatment-related factors. Proton therapy remains experimental and is currently being evaluated in a randomized trial.

Target Delineation. Although CT scans can identify adjacent organs and structures, it may be limited in defining the extent of the primary tumor. Leong and colleagues⁴⁶³ have demonstrated that the addition of PET/CT scan information for treatment planning improved the identification of the gross tumor volume (GTV). The GTV based on CT scan information alone excluded PET-avid disease in 11 of 16 patients (69%), 5 of whom would have resulted in a geographic miss of gross tumor. Thus, in many centers, it is

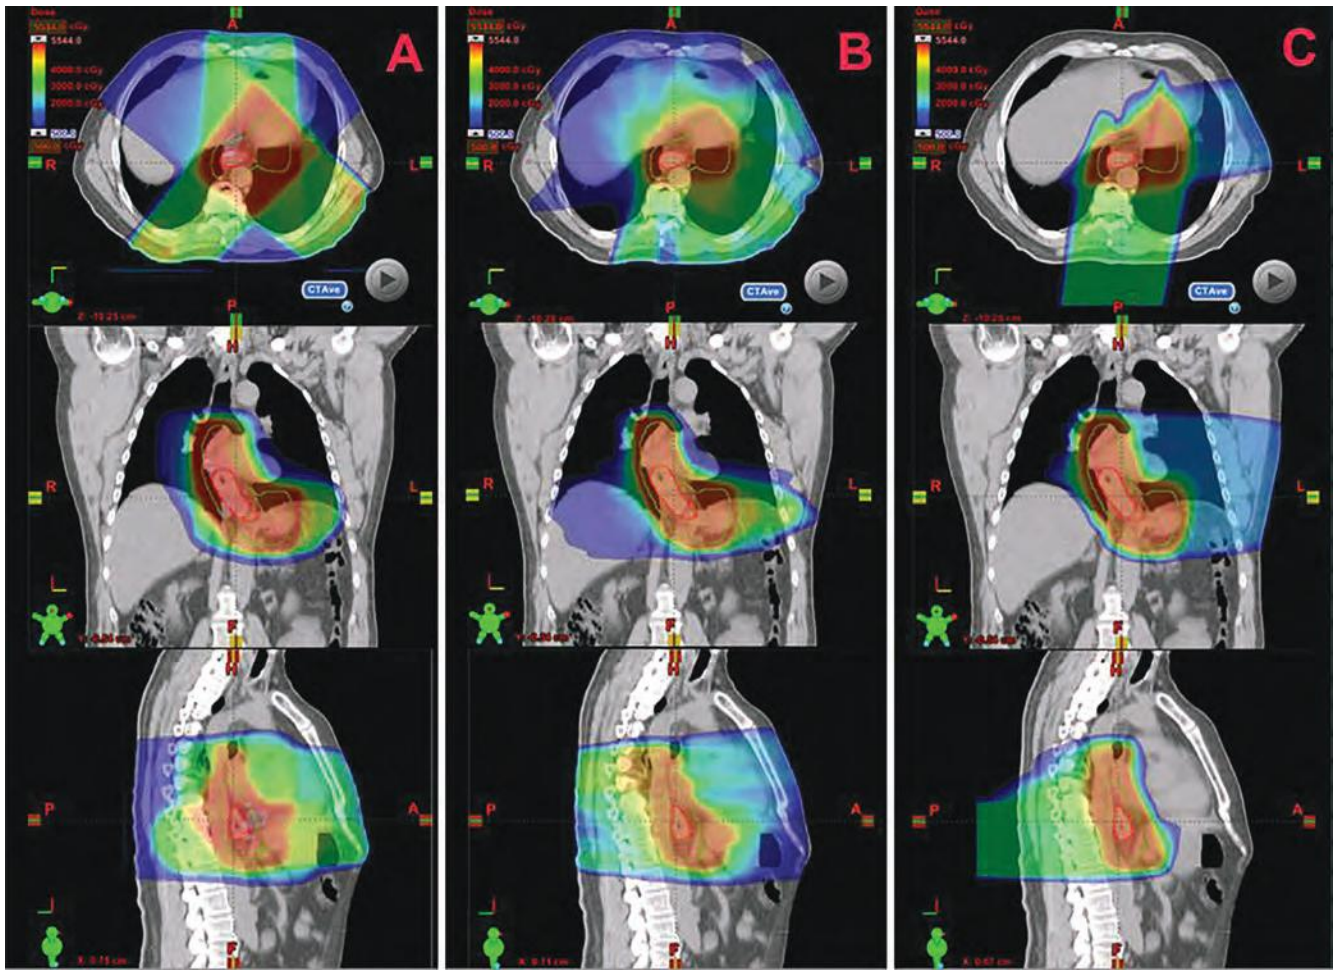

Figure 45.14 Comparative radiation treatment plans. (A) 3D-CRT, (B) IMRT, and (C) proton beam comparison between treatment modalities. In this selected case, both IMRT and protons provide improved lung and cardiac sparing compared to 3D-CRT. Proton beam decreases liver dose compared to other modalities. (Modified from Zhang Z, Liao Z, Jin J, et al. Dose response relationship in locoregional control for patients with stage II–III esophageal cancer treated with concurrent chemotherapy and radiotherapy. *Int J Radiat Oncol Biol Phys* 2005;61:656–664.)

customary to obtain pretreatment FDG-PET scans, not only to identify patients with occult metastatic disease, but also to assist in target delineation. Conversely, MRI has also been suggested to delineate esophageal tumors, although initial studies showed limited benefit in tumor or positive lymph node delineation.⁴⁶⁴ Thus, the use of MRI in this context remains experimental. Thus, the current recommendation for target delineation includes using contrasted CT and EGD/EUS findings, as well as FDG-PET.

Limiting Toxicity of Chemoradiation. Depending on the location of the primary tumor, there are a number of sensitive organs that will be in the radiation field. Specifically, the most well-studied organs at risk in the context of treating esophageal cancer include the lungs and heart. Radiation pneumonitis is clearly linked to the dose and volume of lung treated. Various single dosimetric parameters have been proposed to estimate the probability of developing radiation pneumonitis after radiotherapy.^{428,465–469} Investigators from the Netherlands compared different normal tissue complication probability (NTCP) models to predict radiation pneumonitis.⁴⁶⁸ Using the observed incidence of radiation pneumonitis among breast cancer, malignant lymphoma, and inoperable non-small-cell lung cancer (NSCLC) patients, they found that the underlying local dose-effect relation for radiation pneumonitis was linear. This was better represented by the mean lung dose (MLD) model, rather than a step function model represented by a threshold dose such as V20. In their patient population, the MLD

was the most accurate predictor for the incidence of radiation pneumonitis. Willner and colleagues⁴⁶⁶ performed an analysis of pneumonitis risk from dose volume histogram (DVH) parameters among patients treated with 3D conformal radiotherapy.⁴⁶⁶ Their data indicated that it is reasonable to disperse the dose outside the target volume over large areas in order to reduce the volumes of lung receiving >40 Gy. They found that reducing the high-dose volume reduces the pneumonitis rate more than a corresponding reduction in the low-dose regions of the DVH. Additionally, Konksi and colleagues⁴⁷⁰ were able to correlate cardiac toxicity to dosimetric and patient factors. Specifically they recommended a threshold of V20, V30, and V40 below 70%, 65%, and 60%, respectively, to decrease symptomatic cardiac toxicity. In general, practice a MLD <20 Gy is standard. Cardiac dose constraints are not as clearly defined, but a V30 <35% is reasonable.

In the palliative setting, there are a variety of radiation-treatment regimens.⁴⁷¹ The goal is rapid palliation of symptoms and the most common approach is to treat anteroposteriorly and postero-anteriorly, including the primary tumor with 2-cm margins, in 10 3-Gy fractions to a total dose of 30 Gy.

Treatment of Metastatic Disease

A variety of single-agent and combination chemotherapy regimens have been evaluated in patients with recurrent or metastatic

carcinoma of the esophagus. Phase II clinical trials in this population have identified drugs with activity that have been integrated into combined modality regimens for the treatment of earlier stage disease. Standard criteria for evaluating treatment response require that serial measurement of disease be possible. For the esophageal cancer patient with metastatic disease to distant organ sites or lymph nodes, treatment response can be reliably assessed using spiral CT scans or MRI. The serial tumor measurement for response assessments in patients with disease limited to the esophagus is less reliable. An endoscopy with brushings and biopsy may be performed to confirm a clinically determined complete response; however, a biopsy is subject to sampling error, and biopsy findings are not a reliable indicator of complete histologic resolution of disease. Whole-body FDG-PET performed before and during or after chemotherapy may be a valuable noninvasive method of predicting tumor response and a favorable treatment outcome. Several studies have shown that a reduction in tumor FDG uptake (median decrease in standardized uptake value) correlates with response and longer survival.^{154,158,327} Until the mid-1990s, the accumulated experience with chemotherapy was almost entirely in patients with squamous cell tumors. With the rising incidence of adenocarcinoma of the distal esophagus, GEJ, and cardia in the United States and Western industrialized countries, patients with this histologic type now make up more than half of referrals for chemotherapy. Most trials of new agents and combined modality regimens now include patients with both tumor types. Modern chemotherapy trials in advanced disease also treat gastric adenocarcinoma in concert with adenocarcinoma of the GEJ and distal esophagus, and some trials also include squamous esophageal cancer.

Single-Agent Chemotherapy

Studies of single-agent chemotherapy for esophageal cancer are summarized here. Response data for many of the older drugs have come from broad phase I and II trials conducted in the 1970s and 1980s, which included small numbers of esophageal cancer patients.⁴⁷²⁻⁴⁸¹ Bleomycin, 5-FU, mitomycin, and cisplatin have been used most frequently because of their single-agent activity and additive or synergistic effects with radiation. Because of the potential for pulmonary toxicity, bleomycin is no longer included in combination regimens, having been replaced by 5-FU. Similarly, mitomycin is used less often because of its toxicity profile, which includes hemolytic-uremic syndrome and cumulative myelosuppression.

Seven trials examined the use of cisplatin for single-agent therapy in esophageal cancer patients,^{479,482-487} six of which used dosages ranging from 50 to 120 mg/m² every 3 to 4 weeks. The cumulative response rate in patients with metastatic or recurrent disease was 21%. Vinorelbine is a semisynthetic vinca alkaloid that has less neurotoxicity than vincristine and vinblastine. Phase II trials in metastatic squamous cell cancer of the esophagus report response rates of 20% to 25% using weekly or biweekly dosing schedules.^{488,489} In a subsequent trial, Conroy et al.⁴⁹⁰ evaluated the doublet of vinorelbine and cisplatin. A total of 71 patients with metastatic squamous cell cancer were treated, and a 34% response rate was observed. Vinorelbine was evaluated in a phase II trial in 29 patients with adenocarcinoma of the esophagus who had failed prior chemotherapy, with minor activity (7% response rate) observed.⁴⁹¹

The taxane paclitaxel has been tested in both adenocarcinoma and squamous cell carcinoma of the esophagus. Paclitaxel promotes the stabilization of microtubules and is a cycle-specific agent affecting cells in the G2/M phase. Paclitaxel also enhances radiation effects and may be both concentration and schedule dependent.⁴⁹² Three trials of single-agent paclitaxel have been reported. One used the maximum tolerable dose of 250 mg/m², derived from initial phase I trials using a 24-hour infusion schedule.⁴⁹³ The overall response rate was 32% (34% in 33 patients with adenocarcinoma, and 28% in 18 patients with squamous cell

carcinoma). The second trial tested a regimen of 140 mg/m² infused during 96 hours in patients previously treated using a shorter infusion schedule of paclitaxel-containing combination chemotherapy.⁴⁹⁴ No responses were observed. The third trial evaluated single-agent paclitaxel administered by a weekly 1-hour infusion at a dose of 80 mg/m² in a large multicenter phase 2 setting.⁴⁹⁵ A modest response rate of 15% was observed in 65 patients without prior chemotherapy treatment (16% in the 50 patients treated with adenocarcinoma and 13% in the 15 patients treated with squamous cell carcinoma). Limited activity (5%) was seen in patients with prior chemotherapy. Despite the low response rate, the median survival was 274 days, and toxicity, including hematologic toxicity, was minimal.

Docetaxel was evaluated at a dose of 100 mg/m², every 3 weeks in a combined esophageal and gastric cancer trial treating 33 patients with gastric cancer and 8 patients with esophageal adenocarcinoma.⁴⁹⁶ Two of the eight patients (25%) with esophageal adenocarcinoma had a major response. Overall, grade 4 neutropenia occurred in 88% of patients and neutropenic fever in 46%. A larger trial of docetaxel 75 mg/m² in 22 patients with esophageal adenocarcinoma reported a response rate of 18% in chemotherapy-naïve patients and no responses in previously treated patients.⁴⁹⁶ Febrile neutropenia occurred in 32% of patients. A recent trial of 70 mg/m² every 3 weeks in 49 patients with squamous cell carcinoma reported a 20% response rate.⁴⁹⁷ Eighty-eight percent of patients had grade 3 or 4 neutropenia and 18% had febrile neutropenia.

Drugs that have been adequately tested in squamous cell cancer of the esophagus and have response rates less than 5% are the methotrexate analog dichloromethotrexate⁴⁹⁸ and trimetrexate,^{499,500} and etoposide,^{501,502} ifosfamide,^{503,504} and carboplatin.^{505,506} A more contemporary study of etoposide in untreated patients with squamous cell carcinoma reported a response rate of 19% (5 of 26 patients).⁵⁰⁷ Carboplatin has been studied in both adenocarcinoma and squamous cell carcinoma, and, in contrast to the activity of a single agent, responses to carboplatin were observed in only 3 of 59 chemotherapy-naïve patients. Therefore, substitution of single-agent carboplatin for cisplatin is not recommended when treating patients with either adenocarcinomas or squamous cell carcinomas of the esophagus. Nonetheless, carboplatin combination regimens used as part of combination chemotherapy, in chemoradiation (as previously discussed) and in metastatic disease regimens (discussed later), appear to have comparable activity to cisplatin-based therapy.

Topotecan and gemcitabine have been separately evaluated in both histologic tumor types and have been shown to be inactive.⁵⁰⁸⁻⁵¹⁰ The topoisomerase II inhibitor irinotecan has been evaluated in two phase II trials in adenocarcinoma of the stomach and GEJ, with a response rate of 15% observed.^{511,512}

Combined-Agent Chemotherapy

Older trials (before the mid-1990s) and those in Europe were almost exclusively limited to patients with squamous cell carcinoma. Because esophageal cancer is a relatively uncommon malignancy, many studies include a heterogeneous population of treatment-naïve patients with locally advanced intrathoracic disease as well as patients with recurrent or metastatic disease. Not only is there variation in the patient population, but more recent trials usually limit eligibility to patients with no prior chemotherapy and performance status of 0 or 1. Thus, in the absence of comparative trials, newer regimens may appear more effective.

Most series consist of small numbers of patients; therefore, the 95% CIs are large and nearly all responses are partial. On average, the duration of response ranges from 3 to 6 months.

Trials conducted in the 1980s testing three-drug regimens such as cisplatin, bleomycin, and vindesine^{255,513} and cisplatin and mitoguanzone combined with vindesine⁵¹⁴ or vinblastine⁵¹⁵ yielded response rates of 30% to 40% in patients with squamous cell carcinoma. Toxicity was primarily moderate myelosuppression. Bleomycin and

C, cisplatin; S, squamous cell carcinoma; ECF, epirubicin/cisplatin; FAMTX, 5-FU/doxorubicin/methotrexate; A, adenocarcinoma; EOX, epirubicin/cisplatin or oxaliplatin/5-FU or capecitabine; O, oxaliplatin; Cape, capecitabine; D, docetaxel; Irino, irinotecan.

mitoguazone were subsequently replaced by 5-FU to reduce toxicity and to take advantage of its synergistic activity with cisplatin.

The two-drug combination of cisplatin (100 mg/m² on day 1) and 5-FU (1,000 mg/m² per day continuous infusion for 96 to 120 hours) has been the standard regimen for 2 decades to treat patients with either squamous cell carcinoma or adenocarcinoma. A 35% response rate was observed in patients with metastatic, recurrent, or locally advanced incurable squamous cell cancer of the esophagus.⁴⁸³ Higher response rates (in the 40% to 60% range) were reported in trials administering two or three cycles of cisplatin and 5-FU as induction therapy before surgery. The difference in response rates may be related to better performance status, better nutrition, and smaller volume disease in the surgical candidates. Despite the common use in the oncology community of the combination of 5-FU and cisplatin for the treatment of esophageal carcinoma, only one trial conducted by the EORTC has directly addressed the issue of the comparative efficacy of single-agent cisplatin and the combination of 5-FU and cisplatin (Table 45.9).⁴⁸³ Patients with locally advanced or metastatic squamous cell carcinoma were randomly assigned to receive either cisplatin (100 mg/m²) plus continuous-infusion 5-FU (1,000 mg/m² per day, days 1 to 5) or to cisplatin (100 mg/m²) alone, with both regimens repeated every 3 weeks. The cisplatin/5-FU arm had a higher response rate (35%) and better median survival (33 weeks) than the cisplatin arm (19% and 28 weeks, respectively), but these findings were not statistically significant. Cisplatin/5-FU was also more toxic, with 16% treatment-related deaths for the combination.

Cisplatin in combination with tegafur uracil (UFT), an oral 5-FU pro-drug combining tegafur with uracil, an inhibitor of the enzyme dihydropyrimidine dehydrogenase that degrades 5-FU,

has also been evaluated in esophageal cancer. A response rate of 46% was reported.⁵¹⁶

Recent phase III trials have compared the addition of a third agent to cisplatin/5-FU versus cisplatin/5-FU alone. The Royal Marsden group developed the ECF regimen, a combination of epirubicin (50 mg/m²) and cisplatin (60 mg/m²) every 3 weeks in combination with daily protracted continuous infusion 5-FU (200 mg/m² per day) in gastric cancer. The ECF regimen was compared in a phase III trial in gastric and GEJ adenocarcinoma with a bolus regimen of 5-FU, doxorubicin, and methotrexate (FAMTX) (see Table 45.9).⁵¹⁷ The ECF regimen resulted in a superior response rate (45% versus 21%), failure-free survival (7.4 months versus 3.4 months), and median survival (8.9 months versus 5.7 months) in comparison with FAMTX. The ECF regimen had a tolerable toxicity profile, with less than 10% rates of grade 3 or 4 diarrhea or stomatitis. A more recent trial treating nearly 600 patients with advanced esophageal squamous and adenocarcinoma and gastric adenocarcinoma compared the ECF regimen with a similar regimen substituting mitomycin (7 mg/m² every 6 weeks) for epirubicin (see Table 45.9).⁵¹⁸ This trial validated the previously reported response rate and median survival for the ECF regimen (42%, 9.4 months), but the response rate and median survival observed for the mitomycin combination regimen (44%, 8.7 months) were identical to those of ECF. Given that there was no difference in efficacy for the epirubicin- versus mitomycin-containing arms, this study raises the question of whether or not the addition of a third agent makes a difference in outcome when combined with cisplatin and protracted infusion 5-FU. Of the 533 patients enrolled in this trial, 40 had squamous cell carcinoma of the esophagus and the remainder had adenocarcinoma (125, esophagus; 125, gastroesophageal

junction; 243, stomach). There was a significantly higher response rate among patients with GEJ cancers than among those with distal gastric cancers (48% versus 37%).

Oxaliplatin, as a potential substitute for cisplatin, and oral capecitabine, as a substitute for 5-FU, have been explored in phase II trials⁵¹⁹ and, more recently, phase III randomized trials in esophageal and gastric adenocarcinoma (see Table 45.9). Cunningham et al.⁵²⁰ reported results of a 1,000 patient phase III trial in esophageal squamous cell and adenocarcinoma and gastric cancer, evaluating the frontline use of oxaliplatin or capecitabine. This trial compared conventional ECF with the substitution of capecitabine for infusional 5-FU, and oxaliplatin for cisplatin. The trial employed a two-by-two design, with the control arm ECF, and the experimental arms including capecitabine (625 mg/m² twice daily) substituted for infusional 5-FU; oxaliplatin (130 mg/m²) substituted for cisplatin; and a fourth arm with a substitution of both capecitabine and oxaliplatin. Capecitabine was found to be noninferior to 5-FU, and oxaliplatin noninferior to cisplatin, with comparable rates of antitumor response and progression-free survival across the four treatment arms. A toxicity analysis favored oxaliplatin over cisplatin for neutropenia, alopecia, renal toxicity, and thromboembolism. In a planned comparison of ECF to EOX (epirubicin, oxaliplatin, capecitabine), median survival was superior for EOX (11.2 months versus 9.9 months; HR, 0.80; *p* = 0.02). A second phase III trial from the German AIO group compared infusional 5-FU (24-hour infusion) plus leucovorin combined with either oxaliplatin (85 mg/m²) or cisplatin (50 mg/m²) once every 2 weeks in 220 patients with metastatic gastroesophageal adenocarcinoma.⁵²¹ Like the Cunningham et al. trial, oxaliplatin was found to be noninferior to cisplatin. Oxaliplatin caused significantly less nausea and vomiting, fatigue, renal toxicity, and thromboembolism. Remarkable on both arms of this trial was the relatively low level of grade 3 or 4 toxicities in all categories, running less than 10% to 15%, which was likely due to the 2 weekly schedule of chemotherapy mimicking colorectal cancer scheduling of chemotherapy. Response rates (24.5% to 34.8%), progression-free (3.9 months versus 5.8 months), and overall survival (8.8 months versus 10.7 months) were comparable between the two treatment arms, although all end points trended higher on the oxaliplatin arm. Lastly, a third phase III trial reported by Kang et al.⁵²² compared capecitabine (1,000 mg/m² twice a day for 14 days to 5-FU (800 mg/m² per day continuous infusion) for 5 days, cycled every 3 weeks with cisplatin (80 mg/m²). Like the Cunningham et al. trial, capecitabine was found to be noninferior to 5-FU. Rates of toxicity on the treatment arms were similar, as were measures of progression-free (5.0 months versus 5.6 months) and overall survival (9.3 months versus 10.5 months). Based on the results of these three phase III trials, the substitution of oxaliplatin for cisplatin, or capecitabine for 5-FU, seems justified. The two-drug regimens in the Al-Batran et al.⁵²¹ and Kang et al.⁵²² trials had favorable toxicity profiles and efficacy compared to the three drug regimens of Cunningham et al., and whether or not epirubicin is required as part of therapy in metastatic disease is unclear.

An alternative oral 5-FU agent, S-1, combines the 5-FU prodrug tegafur with a bowel protectant (otercil) and an inhibitor of dihydropyrimidine dehydrogenase (gimeracil). A phase III trial conducted in Japan evaluated S-1 40 to 60 mg twice a day for 3 weeks as a single agent, versus S-1 plus cisplatin (60 mg/m²), cycled once every 5 weeks, in advanced gastric cancer. S-1 plus cisplatin was superior to S-1 alone, with improved rates of response (54% versus 31%), progression-free (6 months versus 4 months), and overall survival (13 months versus 11 months).⁵²³ Based on encouraging data for S-1, a phase III superiority trial comparing S-1 50 mg/m² in two daily divided doses for 21 days was compared to infusional 5-FU 1,000 mg/m² per day for 5 days, cycled every 28 days (see Table 45.9).⁵²⁴ Both arms were combined with cisplatin, with a lower dose of cisplatin combined with S-1 (75 mg/m²) compared to the 5-FU arm (100 mg/m²). A lower dose of S-1 than that used in the Japanese trials was mandated due to greater toxicity for S-1 reported in Western patients in prior phase I and II trials. The trial failed to demonstrate superiority for the S-1 arm, with

equivalent rates of overall survival (7.9 months versus 8.6 months). The S-1 arm had less toxicity than 5-FU, but the lesser cisplatin dose likely accounted for much of the toxicity differences between the treatment arms. Whether S-1 will be adopted in practice in Western countries has yet to be established.

The addition of docetaxel as a third agent added to 5-FU and cisplatin has also recently been reported in a phase III trial of GEJ and gastric cancer (see Table 45.9). 5-FU dosed at 1,000 mg/m² by continuous infusion during 5 days combined with cisplatin (100 mg/m²) was compared with cisplatin (75 mg/m²), 5-FU (750 mg/m²) by continuous infusion during 5 days, and docetaxel (75 mg/m²) in 445 patients with metastatic gastric or GEJ adenocarcinoma.⁵²⁵ Docetaxel resulted in a higher response rate and time to progression (36%, 5.6 months) compared with 5-FU and cisplatin (26%, 3.7 months), but only a marginal median survival improvement (0.6 months) was noted for three-drug therapy. Toxicity was substantial in both treatment arms, including hematologic and gastrointestinal toxicity, with 80% of patients receiving the three-drug combination experiencing grade 3 or 4 neutropenia. The recent trials of 5-FU infusion combination chemotherapy indicate improved therapy tolerance and potentially enhanced antitumor activity, employing either a once every 2 week or a more protracted infusion of 5-FU as in the ECF regimen. The addition of a third agent, including epirubicin or docetaxel, to 5-FU and cisplatin may modestly increase response rates and survival, but, in the case of docetaxel combination therapy, may result in substantial therapy-related toxicity. The use of relatively high and relatively toxic doses of cisplatin (75 to 100 mg/m²) is also called into question, given data from the British phase III ECF trials that indicate potential better therapy tolerance for 60 mg/m² without evident compromising of treatment efficacy. The tolerance of a three-drug regimen may also be influenced by patient age. In a phase III trial targeting 143 patients with esophagogastric cancer 65 years or older, Al-Batran and colleagues⁵²⁶ compared a regimen of biweekly infusional 5-FU and oxaliplatin with or without the addition of docetaxel (see Table 45.9). A higher response rate was reported for triplet therapy with no impact on overall survival, and resulted in much higher rates of toxicity and an actual detriment in quality of life measures compared to two-drug therapy.

Five trials using interferon- α_2a (IFN- α_2a) as a biomodulator of 5-FU suggested possible benefit.⁵²⁷⁻⁵³¹ These phase 2 trials combined IFN- α_2a with 5-FU and with cisplatin combined with continuous-infusion 5-FU, with response rates reported ranging from 27% to 50%, with a suggestion of higher response rates seen in squamous cell carcinoma. Etoposide and cisplatin with or without 5-FU have also undergone a phase II evaluation.⁵³²⁻⁵³⁴ Combination regimens that include paclitaxel have been evaluated in esophageal cancer patients. In three phase II trials of paclitaxel and cisplatin, response rates ranged from 43% to 50%; activity was comparable in both histologic tumor types, often with severe hematologic toxicity.⁵³⁵⁻⁵³⁷ A phase I trial of weekly carboplatin dosed from an area under the curve of 2 to 5 combined with a 1-hour infusion of paclitaxel, 100 mg/m², in 40 patients with advanced esophageal and GEJ cancer had an overall response rate of 54%.⁵³⁸

The three-drug combination of paclitaxel (175 mg/m², 3-hour infusion), combined with cisplatin (20 mg/m² daily days 1-5) and 5-FU (1,000 mg/m² per day continuous infusion \times 120 hours) was evaluated in a multicenter 60 patient trial.⁵³⁹ A 48% response rate was reported (56% in patients with squamous cell cancer and 46% in patients with adenocarcinoma). Toxicity resulted in unplanned hospitalizations for 48% of patients.

Although the dose and schedule of paclitaxel in combination with other active drugs varies among phase II trials, shorter infusion schedules of paclitaxel, in particular the weekly 1-hour schedule, result in less myelotoxicity.

Other regimens of interest include those containing irinotecan. First reported was the doublet of irinotecan and cisplatin administered in low dose on a weekly schedule.⁵⁴⁰ In vitro studies demonstrated sequence-dependent synergy for cisplatin followed by irinotecan, which prevents the removal of cisplatin-induced DNA interstrand cross-links. Two trials yielded encouraging results (51% to

57% response) with a regimen of cisplatin (30 mg/m²) followed by irinotecan (65 mg/m²) administered weekly for 4 weeks, repeated every 6 weeks in adenocarcinoma and squamous cancer.^{540,541} Dysphagia and global quality of life were improved in the majority of patients in one of these trials.⁵⁴⁰ In both studies, toxicity consisted of myelosuppression, diarrhea, and fatigue. Irinotecan 50 mg/m² combined with weekly cisplatin 25 mg/m² and docetaxel 30 mg/m², days 1 and 8 every 21 days, was studied in a phase II trial in 39 patients with esophagogastric cancer.⁵⁴² An encouraging response rate of 54% was observed, with tolerable rates of grade 3 and 4 neutropenia (21%) and diarrhea (26%). However, a recent randomized phase II trial reported only in abstract form compared the chemotherapy regimens FOLFOX, irinotecan and cisplatin, and ECF, all combined with the EGFR-targeted agent cetuximab (Table 45.10).⁵⁴³ The FOLFOX and ECF arms had similar response rates and overall survival, and the toxicity analysis favored the FOLFOX arm, and has led to further questioning of the contribution of epirubicin to a two-drug combination of oxaliplatin and a fluorinated pyrimidine. Notable, however, was the inferior performance of the irinotecan–cisplatin arm, which had the lowest rates of response and overall survival.

Recent studies exploring non–cisplatin-containing combination regimens have employed the taxanes and irinotecan. Although these trials have indicated encouraging response rates in the phase II setting, substantial hematologic and diarrheal toxicities of these regimens may not offer an advantage over the older cisplatin-containing regimens.^{544–548} Docetaxel has been evaluated in combination with irinotecan in four recent phase II trials. Two trials evaluated irinotecan doses of 100 to 160 mg/m² and docetaxel doses of 50 to 60 mg/m² administered once every 3 weeks. Two trials evaluated the day 1 and day 8 schedule of irinotecan (50 to 55 mg/m²) and docetaxel (25 to 35 mg/m²) cycled every 3 weeks. Response rates range from 13 to 30 hematologic toxicity, which exceeded 50% in patients treated on the schedule of once every 3 weeks, seemed to be less using the day 1 and day 8 schedule compared with the once every 3 weeks schedule.

A phase III comparison of cisplatin and infusional 5-FU to the combination of irinotecan and infusional 5-FU was recently

reported in advanced esophagogastric cancer (see Table 45.9).⁵⁴⁹ Response rates (25.8% to 31.8%) and progression-free (4.2 months versus 5.0 months), and overall survival (8.7 months versus 9.0 months) were comparable for the two regimens. Toxicity favored the irinotecan 5-FU arm. Data from this trial and the oxaliplatin-based studies conducted in Europe have led to greater utilization of both irinotecan and oxaliplatin in combination with infusional 5-FU for the treatment of advanced esophagogastric cancer at European centers.

Docetaxel and either vinorelbine or capecitabine were evaluated in phase II trials in squamous cell carcinoma^{550,551} with response rates of 46% to 60%. In summary, recent trials of combination regimens that include paclitaxel or irinotecan appear to have comparable response rates to previous regimens; however, the duration of response remains brief. In addition, the toxicities recorded in some of these phase II single-institution experiences have been excessive.

Targeted Agents

Phase III trials of targeted agents studied alone or in combination with chemotherapy are outlined in Table 45.10. Validation of the activity of a growth factor receptor–targeted agent, trastuzumab, was recently achieved in esophagogastric cancer (see Table 45.10).⁵⁵² Over 3,800 patients with gastric or GEJ adenocarcinoma were screened for overexpression of the HER2 receptor by fluorescence in situ hybridization (FISH) and immunohistochemistry; 22.1% tested positive. Five hundred ninety-four patients were ultimately randomized to chemotherapy alone with (1) capecitabine 1,000 mg/m² twice a day for 14 days or (2) infusional 5-FU 800 mg/m² per day for 5 days, combined with cisplatin 80 mg/m² on day 1, cycled every 3 weeks, or to chemotherapy plus trastuzumab 6 mg/kg once every 3 weeks. The majority of patients received capecitabine plus cisplatin as the chemotherapy regimen. All end points were improved with the addition of trastuzumab to chemotherapy, including antitumor response (47.3% versus 34.5%), progression-free survival (6.7 months versus 5.5 months), and overall survival (13.8 months versus 11.1 months) (HR, 0.74; *p* = 0.0046). Toxicity was comparable for the two

TABLE 45.10

Phase II–III Randomized Trials of Targeted Agents

Regimen	Patients (N)	Histologic Type	Response Rate (%)	Overall Survival (months)	Reference
Cape-C +/- trastuzumab	584	A	47 35	13.8 11.1	552
FOLFOX vs Irino-C vs ECF + cetuximab	210	A/S	54 46 58	12.4 8.9 11.5	561
EOX +/- panitumumab	553	A	46 42	8.8 11.3	562
Cape-C +/- cetuximab	904	A	29 29	10 10	563
5-FU-C +/- cetuximab	62	S	19 13	9.5 5.5	564
Cape-C +/- bevacizumab	774	A	46 37	12.1 10.1	566
Ramucirumab vs placebo	355	A	3 3	5.2 3.8	567
Everolimus vs placebo	656	A	4 2	5.4 4.3	568

Cape, capecitabine; C, cisplatin; A, adenocarcinoma; FOLFOX, 5-FU + oxaliplatin; Irino-C, irinotecan-cisplatin; ECF, epirubicin/cisplatin; S, squamous cell carcinoma; EOX, epirubicin/cisplatin or oxaliplatin/5-FU or capecitabine.

treatment arms, with no significant cardiotoxicity from trastuzumab other than an asymptomatic, less than 10% drop in left ventricular ejection fraction, which was slightly higher on the trastuzumab arm compared to chemotherapy alone (4.6% versus 1.1%). Based on these results, the inclusion of trastuzumab in the first-line treatment of HER2+ metastatic esophagogastric cancer should now be considered. Based on these data and pilot data combining trastuzumab with chemoradiotherapy in esophageal cancer RTOG has undertaken a phase III trial (RTOG-1010) comparing preoperative chemoradiotherapy with carboplatin and paclitaxel with or without trastuzumab in locally advanced adenocarcinoma of the esophagus and GEJ, as discussed previously.

In patients with localized esophageal adenocarcinoma, HER2+ disease was associated with a significantly lower tumor grade, earlier stage of disease with fewer malignant lymph nodes, and the presence of Barrett's esophagus. These features of HER2+ localized esophageal cancer led to an independent improvement in disease-specific survival (HR, 0.54; 95% CI, 0.35 to 0.84) and overall survival ($p = 0.0022$), suggesting that HER2+ is a favorable prognostic feature in localized esophageal adenocarcinoma.⁵⁵³

With evidence for effectiveness of agents targeting the EGFR in NSCLC (including receptor-associated tyrosine-kinase inhibitors) and in colorectal cancer (including monoclonal antibodies blocking the binding of the EGFR ligand), recent phase II trials have evaluated EGFR-targeted agents in esophageal squamous cell and adenocarcinoma. A recent phase II trial of the EGFR tyrosine-kinase inhibitor gefitinib failed to indicate activity for esophageal adenocarcinoma, but limited activity was observed in squamous cell cancer.⁵⁵⁴ A second trial indicated some limited activity for adenocarcinoma,⁵⁵⁵ but in both trials, most patients experienced early disease progression. A phase II trial of the EGFR tyrosine-kinase inhibitor erlotinib reported a 9% response rate in 44 patients with adenocarcinoma of the GEJ.⁵⁵⁶ With these mixed phase II trial results, a recent negative trial for an EGFR tyrosine-kinase inhibitor was reported only in abstract form by Dutton et al.⁵⁵⁷ The trial compared best supportive care to treatment with gefitinib in patients with esophageal and GEJ adenocarcinomas progressing on conventional chemotherapy. In this large trial, no difference in overall survival could be demonstrated for gefitinib compared to supportive care alone.

Monoclonal antibodies targeting the EGFR, including cetuximab and panitumumab, have proceeded to phase III trial investigation combined with chemotherapy, based on promising data from phase II trials.⁵⁵⁸⁻⁵⁶⁰ The randomized phase II trial conducted by the CALGB and ECOG evaluated three modern chemotherapy regimens combined with cetuximab in the first-line treatment of esophageal and GEJ cancer (see Table 45.10),⁵⁶¹ and was discussed previously. The regimens used were weekly irinotecan-cisplatin, ECF, and FOLFOX (5-FU, leucovorin, and oxaliplatin). The trial indicated comparable response rates, progression-free survival, and overall survival for the FOLFOX and ECF plus cetuximab arms, whereas the irinotecan-cisplatin arm was inferior. The final results of this study may not contribute much to the debate about EGFR-targeted agents, because two large phase III trials of these agents combined with chemotherapy failed to improve outcomes. Waddell and colleagues⁵⁶² reported results of the REAL-3 trial in esophagogastric cancer, comparing patient treatment with EOX with or without the EGFR antibody panitumumab (see Table 45.10).⁵⁶² In the 553 patients treated, although response rates for treatment with or without panitumumab were similar, overall survival was significantly inferior on the panitumumab arm (11.3 versus 8.8 months) and progression-free survival trended inferior for panitumumab (7.4 versus 6.0 months). Toxicity rates were higher on the panitumumab arm, and the chemotherapy starting doses were lower with panitumumab than on the chemotherapy alone arm. Prognostic biomarkers studied on the trial included KRAS mutation, PIK3CA kinase mutation, and loss of phosphatase and tensin homolog (PTEN). These markers were affected in a tiny minority of patients, and no clear biomarker has emerged from this trial. The potential deleterious effect of adding an EGFR anti-

body to the treatment of esophagogastric cancer was also seen in a recent chemoradiotherapy trial, discussed earlier, in which adding cetuximab to definitive chemoradiotherapy in esophageal cancer also appeared to worsen outcomes.³⁴⁹ A second negative trial for EGFR-targeted antibodies in advanced disease was reported by Lordick et al. (see Table 45.10).⁵⁶³ The 904 patients with esophagogastric cancer were randomized to treatment with capecitabine and cisplatin with or without cetuximab. Progression-free survival and overall survival also trended inferior on the cetuximab arm (progression-free survival, 5.6 versus 4.4 months; overall survival, 10.7 versus 9.4 months), and response rates were identical (29%). In contrast to these negative trials, Lorenzen et al.⁵⁶⁴ reported results of a small phase II trial in advanced squamous cancer of the esophagus comparing 5-FU-cisplatin with or without cetuximab (see Table 45.10). Outcomes were poor on both arms of the trial; however, response rates and overall survivals were improved on the cetuximab arm (19% versus 13%; 9.5 months versus 5.5 months). A larger phase III trial in squamous cancer of the esophagus is now ongoing (NCT01627379) to evaluate panitumumab combined with 5-FU and cisplatin. RTOG-0436, adding cetuximab to primary chemoradiotherapy in locally advanced esophageal cancer,³⁵⁰ was discussed earlier, and was also a negative trial for the addition of EGFR-targeted therapy.

Another growth factor receptor pathway under active investigation is the vascular endothelial growth factor (VEGF) receptor pathway, based on trials that demonstrate improved effectiveness for chemotherapy in colorectal cancer when combined with the anti-VEGF-A ligand monoclonal antibody bevacizumab. A recent phase II trial combined bevacizumab at a dose of 15 mg/kg every 3 weeks in combination with a day 1 and day 8 schedule of irinotecan (65 mg/m²) and cisplatin (30 mg/m²).⁵⁶⁵ The multicenter trial treated 47 patients treated with metastatic adenocarcinoma of the GEJ and more distal gastric cancer. An encouraging response rate of 65% was observed, with a suggestion of improvement in time to tumor progression (8.9 months) compared with historical controls. A phase III trial combining bevacizumab with either 5-FU or capecitabine plus cisplatin in 774 patients with esophagogastric adenocarcinoma was recently reported by Ohtsu and colleagues (see Table 45.10).⁵⁶⁶ Despite improvements in progression-free survival (5.3 to 6.7 months) and response rate (37% to 46%), a trend toward improvement in overall survival did not reach statistical significance (10.1 to 12.1 months; HR, 0.87; $p = 0.1002$). Another VEGF-targeted agent, ramucirumab, which blocks ligand binding to the receptor VEGF2, indicated a positive effectiveness in refractory esophagogastric cancer compared to placebo.⁵⁶⁷ Fuchs and colleagues⁵⁶⁷ randomized 355 patients progressing on 5-FU or platinum-based chemotherapy to best supportive care plus placebo versus best supportive care plus ramucirumab administered once every 2 weeks. Although no significant antitumor responses were seen, overall survival was significantly improved with ramucirumab (3.8 to 5.2 months) and toxicity was limited to a slight increase in hypertension. Results for studies of the combination of ramucirumab with chemotherapy in first- or second-line treatment are pending publication. The positive results for ramucirumab have led to a resurgent interest in the study of VEGF-targeted agents in esophageal cancer.

Finally, a recent large, placebo-controlled trial in chemotherapy refractory esophagogastric cancer compared placebo to the mammalian target of rapamycin (mTOR)-targeted agent everolimus in 656 patients (see Table 45.10).⁵⁶⁸ Although progression-free survival was slightly improved with everolimus, there was no improvement in overall survival (5.4 months for everolimus versus 4.3 months for placebo).

STAGE-DIRECTED TREATMENT RECOMMENDATIONS

Although level I evidence is lacking to support ironclad recommendations regarding the most effective treatment of patients

grouped by stage in many clinical situations, reasonable trial-generated information exists to suggest appropriate therapeutic interventions for patients grouped under broad staging categories.

Resection remains the standard by which all other treatment options must be measured for patients with high-grade dysplasia in the setting of Barrett's esophagus or T1 disease limited to the mucosa, with the caveat that esophagectomy-associated mortality must be extremely low. EMR may be considered an appropriate first step in addressing patients with mucosa-limited lesions. Intensive long-term endoscopic surveillance for patients with Barrett's esophagus-associated high-grade dysplasia is necessary to limit both cancer- and treatment-related mortality.

An esophagectomy is an appropriate method for treating patients with stage I, II, and III disease. Alternatively, definitive chemoradiation is a therapeutic option for patients with stage II and III disease, especially those who are not considered surgical

candidates or who have squamous cell carcinoma at or above the carina. The high rate of persistent or recurrent local-regional disease after definitive chemoradiation suggests that additional local therapy in the form of surgery may be necessary and beneficial. This potential benefit may be realized only if perioperative mortality is minimized. Preoperative chemoradiation has been proven to be more effective than surgery alone, and is now appropriately embraced by US oncologists for patients with resectable stage IIB and III esophageal cancers. Defining more effective regimens must continue to be the focus of well-designed clinical trials. Post-operative chemoradiation should be reserved for patients with resected adenocarcinoma of the GEJ. Preoperative chemotherapy is an accepted standard of care in the United Kingdom but is still considered investigational in the United States. All patients with unresectable or stage IV disease are ideally suited for clinical trials exploring novel therapeutic agents and approaches.

46 Cancer of the Stomach

Itzhak Avital, Alexander Stojadinovic, Peter W. T. Pisters, David P. Kelsen, and Christopher G. Willett

INTRODUCTION

Adenocarcinoma of the stomach was the leading cause of cancer-related death worldwide through most of the 20th century. It now ranks second only to lung cancer, and an estimated 870,000 new cases are diagnosed annually, and 650,000 deaths (10% of all cancer deaths) worldwide.¹ In 2011, the epidemiologic data on cancer of the stomach was updated. It now ranks fourth after lung cancer, breast cancer, and colorectal cancer. An estimated 989,600 new cases are diagnosed annually, with 738,000 deaths (10% of all cancer deaths) worldwide.² In the West, the incidence of gastric cancer has decreased, potentially because of changes in diet, food preparation, and other environmental factors. The declining incidence has been dramatic in the United States, where this disease ranked sixth as a cause of cancer-related death during the period of 2000 to 2005.³ It is estimated that in 2009, 21,130 new gastric cancer cases were diagnosed in the United States, with approximately 10,600 deaths.³ Data was updated for 2014 where an estimated 22,220 new cases will be diagnosed in the United States, with approximately 10,990 deaths.⁴ Prognosis remains poor except in a few countries. The explanations for this finding are multifactorial. The lack of defined risk factors, disease-specific symptoms, and the low incidence of gastric cancer has contributed to the late stage at diagnosis seen in most Western countries. In Japan, where gastric cancer is endemic, more patients are diagnosed at an early stage, which is reflected in higher overall survival (OS) rates.

The decline in incidence has been limited to noncardia gastric cancers.⁵ The number of newly diagnosed cases of proximal gastric and esophago-gastric junction (EGJ) adenocarcinomas has increased six-fold since the mid-1980s.⁶ These proximal tumors are thought to be biologically more aggressive and more complex to treat. The only chance of cure is complete surgical resection. However, even after what is believed to be a “curative” gastrectomy, disease recurs in the majority of patients. Efforts to improve these poor results have focused on developing effective pre- and postoperative systemic and regional adjuvant therapies. This chapter details the state-of-the-art regarding the origins, screening, diagnosis, treatment, and palliation of this significant worldwide health problem.

ANATOMIC CONSIDERATIONS

The stomach begins at the gastroesophageal junction and ends at the pylorus (Fig. 46.1). Cancers arising from the proximal greater curvature may directly involve the splenic hilum and tail of pancreas, whereas more distal tumors may invade the transverse colon. Proximal cancers may extend into the diaphragm, spleen, or the left lateral segment of the liver. A recent study reported on the potential benefits and harms of complete resection even when the tumor invades adjacent abdominal visceral structures (pT4b).⁷ In this large multicenter cohort series of 2,208 patients who underwent curative intent resection, 206 patients had pT4b tumors and 112 underwent resection of adjacent organs as part of en bloc gastric cancer resection. The overall 5-year survival rate for this group of patients was 27.2%, suggesting that patients do have a chance

at long-term survival if their tumor can be removed en bloc with involved adjacent organs, thereby supporting the role of multivisceral resection if required and technically feasible.⁷

The blood supply to the stomach is extensive and is based on vessels arising from the celiac axis (see Fig. 46.1). The right gastric artery arises from the hepatic artery proper (50% to 68%), left hepatic artery (29% to 40%), or from the common hepatic artery (3.2%). The left gastric artery originates from the celiac axis directly (90%) and may arise from the common hepatic artery (2%), splenic artery (4%), or aorta or from the superior mesenteric artery (3%). Both right and left gastric arteries course along the lesser curvature. Along the greater curvature are the right gastroepiploic artery, which originates from the gastroduodenal artery at the inferior border of the proximal duodenum (rarely from the superior mesenteric artery), and the left gastroepiploic artery (highly variable artery), branching from the distal (72%), inferior, middle splenic artery laterally. The short gastric arteries (vasa brevia, five to seven separate vessels) arise directly from the splenic artery or the left gastroepiploic artery. The posterior (dorsal) gastric artery (17% to 68%) may arise from the splenic artery to supply the distal esophagus, cardia, and fundus. The preservation of any of these vessels in the course of a subtotal gastrectomy for carcinoma is not necessary, and the most proximal few centimeters of remaining stomach are well supplied by collateral flow from the lower segmental esophageal arterial arcade. The rich submucosal blood supply of the stomach is an important factor in its ability to heal rapidly and produce a low incidence of anastomotic disruption following radical gastric resection. The venous drainage of the stomach tends to parallel the arterial supply. The venous efflux ultimately passes through the portal venous system, and this is reflected in the fact that the liver is the primary site for distant metastatic spread.

The lymphatic drainage of the stomach is extensive, and distinct anatomic groups of perigastric lymph nodes have been defined according to their relationship to the stomach and its blood supply. There are six perigastric lymph node groups. In the first echelon (stations 1 through 6) are the right and left pericardial nodes (stations 1 and 2). Along the lesser curvature are the lesser curvature nodes (station 3) and the suprapyloric nodes (station 5). Along the greater curvature, the gastroepiploic nodes or greater curvature nodes (station 4), and the subpyloric nodes (station 6). In the second echelon (stations 7 through 12) are the nodes along named arteries, which include the left gastric, common hepatic, celiac, splenic hilum, splenic artery, and hepatoduodenal lymphatics (stations 7 through 12, respectively), which drain into the celiac and periaortic lymphatics. The third echelon (stations 13 through 16) contains the posterior to pancreatic head, superior mesenteric artery, middle colic artery, and para-aortic lymphatics (stations 13 through 16, respectively). Proximally are the lower esophageal lymph nodes; extensive spread of gastric cancer along the intrathoracic lymph channels may be manifested clinically by a metastatic lymph node in the left supraclavicular fossa (Virchow's node) or left axilla (Irish's node). Tumor spread to the lymphatics in the hepatoduodenal ligament can extend along the falciform ligament and result in subcutaneous periumbilical tumor deposits (Sister Mary Joseph's nodes).

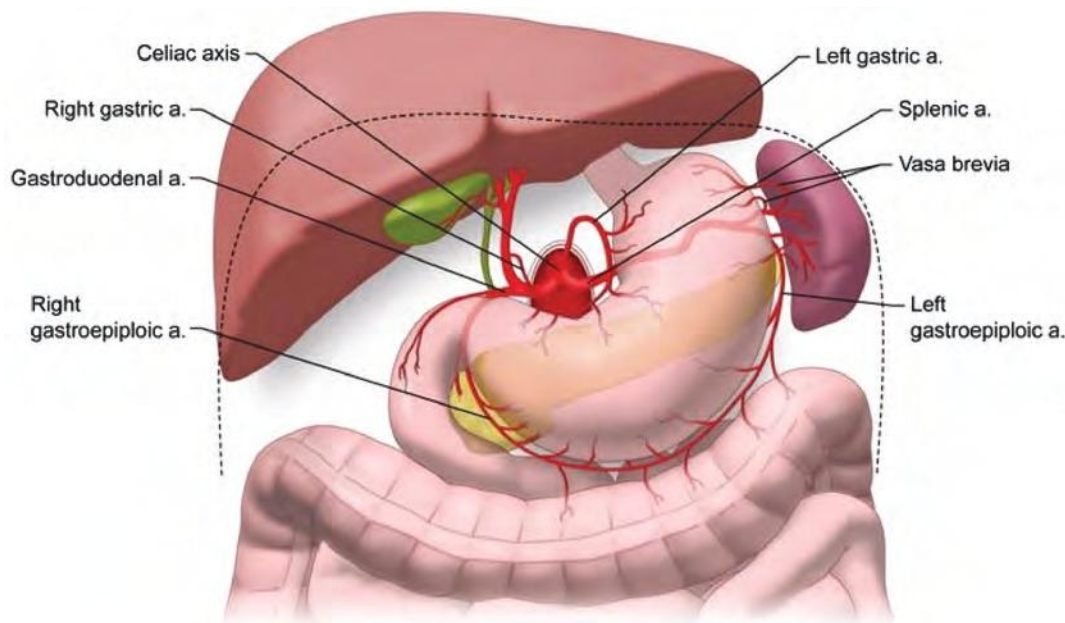

Figure 46.1 Blood supply to the stomach and anatomic relationships of the stomach with other adjacent organs likely to be involved by direct extension of a T4 gastric tumor.

PATHOLOGY AND TUMOR BIOLOGY

Approximately 95% of all gastric cancers are adenocarcinomas. The term *gastric cancer* refers to adenocarcinoma of the stomach. Other malignant tumors are rare and include squamous cell carcinoma, adenoacanthoma, carcinoid tumors, small cell carcinoma, mucinous carcinoma, hepatoid adenocarcinoma, oncocytic (parietal gland) carcinoma, sarcomatoid carcinoma, lymphoepithelioma-like carcinoma, adenocarcinoma with rhabdoid features, gastric carcinoma with osteoclastlike giant cells, neuroendocrine tumor, gastrointestinal stromal tumor, or leiomyosarcoma.⁸ Although no normal lymphoid tissue is found in the gastric mucosa, the stomach is the most common site for lymphomas of the gastrointestinal tract. The increased awareness of association between mucosa-associated lymphoid tissue lymphomas and *Helicobacter pylori* may explain, in part, the rise in incidence,⁹ although the incidence of mucoas-associated lymphoid tissue gastric lymphomas is decreasing likely because of effective treatment against *H. pylori*.¹⁰

In terms of pathogenesis, two new concepts are worth mentioning: bone marrow participation in gastric carcinogenesis and gastric cancer stem cells. It has been hypothesized that the gastric epithelial cells acquiring abnormal phenotype (resembling intestinal epithelium) originate from gastric stem cells localized to the only cell replication zone of the gastric glands (i.e., the isthmus). However, Houghton et al.,¹¹ Stoicov et al.,^{12,13} and Li et al.¹⁴ demonstrated in a rodent model of *Helicobacter*-induced gastric cancer that the entire cancer mass was derived from cells originating in the bone marrow. This interesting phenomenon was observed by other authors studying solid cancers in patients receiving bone marrow transplantation.¹⁵ Recent evidence proposes the existence of cancer stem cells or stemlike cancer cells in various cancers. Although controversial, cancer stem cells are defined as cancer cells with the exclusive ability to initiate tumors, metastasize, and self-renew tumors. In gastric cancer, several investigators suggested the existence of gastric cancer stem cells (i.e., CD44+) and side population cells.^{16,17} These cells showed relative resistance to chemotherapy and radiation, and exclusive ability to initiate tumors. These important observations might lead to novel approaches to the diagnosis and treatment of gastric cancer in the next decade.

HISTOPATHOLOGY

Several staging schemas have been proposed based on the morphologic features of gastric tumors. The Borrmann classification divides gastric cancer into five types depending on macroscopic appearance. Type I represents polypoid or fungating cancers, type II encompasses ulcerating lesions surrounded by elevated borders, type III represents ulcerated lesions infiltrating the gastric wall, type IV includes diffusely infiltrating tumors, and type V gastric cancers are unclassifiable cancers.¹⁸ The gross morphologic appearance of gastric cancer and the degree of histologic differentiation are not independent prognostic variables. Ming¹⁹ has proposed a histomorphologic staging system that divides gastric cancer into either a prognostically favorable expansive type or a poor prognosis infiltrating type. Based on an analysis of 171 gastric cancers, the expansive-type tumors were uniformly polypoid or superficial on gross appearance, whereas the infiltrative tumors were almost always diffuse. Grossly ulcerated lesions were divided between the expansive or infiltrative forms. Broder's classification of gastric cancer grades tumors histologically from 1 (well-differentiated) to 4 (anaplastic). Bearzi and Ranaldi²⁰ have correlated the degree of histologic differentiation with the gross appearance of 41 primary gastric cancers seen on endoscopy. Ninety percent of protruding or superficial cancers were well differentiated (Broder's grade 1), whereas almost half of all ulcerated tumors were poorly differentiated or diffusely infiltrating (Broder's grades 3 and 4).

The most widely used classification of gastric cancer is by Laurén.²¹ It divides gastric cancers into either intestinal or diffuse forms. This classification scheme, based on tumor histology, characterizes two varieties of gastric adenocarcinomas that manifest distinctively different pathology, epidemiology, genetics, and etiologies. The intestinal variety represents a differentiated cancer with a tendency to form glands similar to other sites in the gastrointestinal tract, but in particular the colon type; hence the intestinal type. In contrast, the diffuse form exhibits very little cell cohesion with a predilection for extensive submucosal spread and early metastases. Although the diffuse-type cancers are associated with a worse outcome than the intestinal type, this finding is not independent of tumor, node, and metastasis (TNM) stage. The molecular pathogenesis of these two distinct forms of gastric cancer is also different. Although the intestinal type represents

H. pylori-initiated multistep progression with less defined progressive genetic alterations, the diffuse type main carcinogenic event is loss of expression of E-cadherin (*CDH1* gene). E-cadherin is a molecule involved in cell-to-cell adhesion; loss of its expression leads to noncohesive growth, hence the diffuse type. In tumors that display both intestinal and diffuse phenotypes, the *CDH1* mutation and loss of E-cadherin function are observed only within the diffuse phenotype.²²

PATTERNS OF SPREAD

Carcinomas of the stomach can spread by local extension to involve adjacent structures and can develop lymphatic metastases, peritoneal metastases, and distant metastases. These extensions can occur by the local invasive properties of the tumor, lymphatic spread, or hematogenous dissemination. The initial growth of the tumor occurs by penetration into the gastric wall, extension through the wall, within the wall longitudinally,²³ and subsequent involvement of an increasing percentage of the stomach. The two modes of local extension that can have major therapeutic implications are tumor penetration through the gastric serosa, where the risk of tumor invasion of adjacent structures or peritoneal spread is increased, and lymphatic involvement. Zinniger²⁴ has evaluated spread within the gastric wall and has found a wide variation in its extent. Tumor spread is often through the intramural lymphatics or in the subserosal layers.²³ Local extension can also occur into the esophagus or the duodenum.²⁵ Duodenal extension is rare (0.5% to 1.8% of all resected cases),²⁶ portrays poor prognosis, and is principally through the muscular layer by direct infiltration and through the subserosal lymphatics, but is not generally to any great extent.²⁷ Extension into the esophagus occurs primarily through the submucosal lymphatics.²⁸

Local extension does not occur solely by radial intramural spread but also by deep invasion through the wall to adjacent structures²³ (omentum, spleen, adrenal gland, diaphragm, liver, pancreas, or colon). Many studies report that 60% to 90% of patients had primary tumors penetrating the serosa or invading adjacent organs and that at least 50% had lymphatic metastases. In the largest series reporting on 10,783 patients with gastric cancer from Korea, 57% of the patients had lymph node metastasis, and the average number of involved lymph nodes was five.^{29,30} Of the 1,577 primary gastric cancer cases admitted to Memorial Sloan Kettering Cancer Center (MSKCC) between July 1, 1985, and June 30, 1998, 60% of the 1,221 resected cases had evidence of serosal penetration and 68% had positive nodes. Lymph node metastases were found in 18% of pT1 lesions, and 60% of pT2 lesions after R0 resection in 941 patients. The highest incidence of lymphatic metastasis was seen in tumors diffusely involving the entire stomach. Tumors located at the gastroesophageal junction also had a high incidence relative to other sites.³¹

The pattern of nodal metastases also varies depending on the location of the primary site. In a study, reporting on 1,137 patients with early gastric cancer (EGC), tumors located in the upper, middle, and lower third of the stomach had 12%, 10%, and 8% nodal involvement, respectively. The most common nodal station metastases for the upper, middle, and lower third of the stomach were stations 3 (lesser curvature), 3/4/7 (lesser/greater curvature/left gastric artery), and 3/4/6 (lesser/greater curvature/infrapyloric), respectively.³² Earlier studies that included more advanced gastric cancers showed that the left gastric artery nodes were at increased risk for nodal metastases independent of tumor location.^{32,33}

Gastric cancer recurs in multiple sites, locoregionally and systemically. Patterns of failure are variable. These differences are likely related to the patient cohorts evaluated, the time at which failure was determined, and the method of determination of failure patterns. Recent series from the MSKCC and Korea do shed light on modern patterns of failure.^{31,34} In the report from MSKCC, recurrence patterns of 1,038 patients who underwent

R0 gastrectomy with D2 lymphadenectomy (61%) were analyzed; complete data on recurrence were available in 367 (74%) of 496 patients who experienced recurrence. The locoregional area was involved in 199 (54%) patients. Distant sites were involved in 188 (51%) patients, and peritoneal recurrence was detected in 108 (29%) patients. More than one site of recurrence was detected: distal, peritoneal, and locoregional recurrences in 9 (2.5%); locoregional and peritoneal in 34 (9.3%); locoregional and distant in 61 (16.6%); and distant and peritoneal in 15 (4.1%) patients. On multivariate analysis, peritoneal recurrence was associated with female gender, advanced T stage, and distal and diffuse type tumors; locoregional recurrence was associated with proximal location, early T stage, and intestinal type tumors. In the study from Korea, recurrence patterns were analyzed in 2,038 patients who were treated with potentially curative gastrectomy.³⁴ Of 508 patients who developed recurrence, 33% involved locoregional sites, 44% were peritoneal, and 38% were distant. At time of presentation, 35% of patients presented with distant metastasis, with 4% to 14% having liver metastases.^{35,36}

CLINICAL PRESENTATION AND PRETREATMENT EVALUATION

Signs and Symptoms

Because of the vague, nonspecific symptoms that characterize gastric cancer, many patients are diagnosed with advanced-stage disease. Patients may have a combination of signs and symptoms such as weight loss (22% to 61%)³⁷; anorexia (5% to 40%); fatigue, epigastric discomfort, or pain (62% to 91%); and postprandial fullness, heart burn, indigestion, nausea, and vomiting (6% to 40%). None of these unequivocally indicates gastric cancer. In addition, patients may be asymptomatic (4% to 17%).³⁸ Weight loss and abdominal pain are the most common presenting symptoms at initial encounter.³⁹⁻⁴¹ Weight loss is a common symptom, and its clinical significance should not be underestimated. Dewys et al.⁴² found that in 179 patients with advanced gastric cancer, >80% of patients had a >10% decrease in body weight before diagnosis. Furthermore, patients with weight loss had a significantly shorter survival than did those without weight loss.⁴⁰

In some patients, symptoms may suggest the presence of a lesion at a specific location. Up to 25% of the patients have history/symptoms of peptic ulcer disease.³⁹ A history of dysphagia or pseudoachalasia may indicate the presence of a tumor in the cardia with extension through the gastroesophageal junction.⁴³ Early satiety is an infrequent symptom of gastric cancer but is indicative of a diffusely infiltrative tumor that has resulted in loss of distensibility of the gastric wall. Delayed satiety and vomiting may indicate pyloric involvement. Significant gastrointestinal bleeding is uncommon with gastric cancer; however, hematemesis does occur in approximately 10% to 15% of patients, and anemia in 1% to 12% of patients. Signs and symptoms at presentation are often related to spread of disease. Ascites, jaundice, or a palpable mass indicate incurable disease.⁴⁰ The transverse colon is a potential site of malignant fistulization and obstruction from a gastric primary tumor. Diffuse peritoneal spread of disease frequently produces other sites of intestinal obstruction. A large ovarian mass (Krukenberg's tumor) or a large peritoneal implant in the pelvis (Blumer's shelf), which can produce symptoms of rectal obstruction, may be palpable on pelvic or rectal examination.^{37,44} Nodular metastases in the subcutaneous tissue around the umbilicus (Sister Mary Joseph's node) or in peripheral lymph nodes such as in the supraclavicular area (Virchow's node) or axillary region (Irish's node) represent areas in which a tissue diagnosis can be established with minimal morbidity.⁴⁵ There is no symptom complex that occurs early in the evolution of gastric cancer that can identify individuals for further diagnostic measures. However, alarming symptoms (dysphagia,

weight loss, and palpable abdominal mass) are independently associated with survival; increased number and the specific symptom is associated with mortality.^{40,41}

Screening

A list of risk factors associated with gastric cancer is outlined in Table 46.1. These factors might be used for risk stratification in screening programs. Mass screening programs for gastric cancer have been most successful in high-risk areas, especially in Japan.⁴⁶ A variety of screening tests have been studied in Japanese patients, with a sensitivity and specificity of approximately 90%.⁴⁰ Screening typically includes serology for *H. pylori*, the use of double-contrast barium radiographs, or upper endoscopy with risk stratification (OLGA staging system for gastric cancer risk^{46,47}).

Ohata et al.⁴⁸ reported on 4,655 asymptomatic patients with an average age of 50 years old who were followed for 7.7 years. Atrophic gastritis was identified using pepsinogen and *H. pylori* testing: 2,341 (52%) were *H. pylori*-positive with nonatrophic gastritis, 967 (21%) were *H. pylori*-negative without atrophic gastritis, 1,316 (28%) were *H. pylori*-positive with atrophic gastritis,

and 31 (0.7%) had severe atrophic gastritis. The rates of gastric cancer development per population per year were 107/100,000 for *H. pylori*-positive with nonatrophic gastritis, 0/100,000 for *H. pylori*-negative without atrophic gastritis, 238/100,000 for *H. pylori*-positive with atrophic gastritis, and 871/100,000 for severe atrophic gastritis. Thus the number of endoscopies needed to detect one cancer was 1/1,000, 0/1,000, 1/410, and 1/114, respectively. Similar data were reported on 6,985 patients by Watabe et al.⁴⁹ Surveillance in endemic populations is clinically important because EGC has a very high cure rate with surgical treatment. However, the fact that gastric cancer remains one of the top causes of death in Japan indicates the limitations of a mass-screening program when the entire population at risk is not effectively screened. However, more recent studies indicate that for surveillance programs to be effective and feasible from an economical perspective, they should be instituted only in high-risk populations (>20/100,000 incidence of disease) and include the following components: detection and eradication of *H. pylori*, serum pepsinogen (pepsinogen I/II ratio), endoscopy with biopsy, and risk stratification before and after *H. pylori* eradication using a system such as the OLGA staging system for gastric cancer risk. Such programs are expected to avoid long-term repeated screening of approximately 70% of the population who are at low risk of developing gastric cancer.^{46,50-52} A US study found that screening and eradication of *H. pylori* in Japanese Americans is cost-effective in preventing gastric cancer.⁵³ These findings were confirmed by two studies from the United Kingdom.^{54,55}

TABLE 46.1

Factors Associated with Increased Risk of Developing Stomach Cancer

Acquired Factors

- Nutritional
 - High salt consumption
 - High nitrate consumption
 - Low dietary vitamin A and C
 - Poor food preparation (smoked, salt cured)
 - Lack of refrigeration
 - Poor drinking water (well water)
- Occupational
 - Rubber workers
 - Coal workers
- Cigarette smoking
- *Helicobacter pylori* infection
- Epstein-Barr virus
- Radiation exposure
- Prior gastric surgery for benign gastric ulcer disease
- Prior treatment for mucosa-associated lymphoid tissue lymphoma

Genetic Factors

- Type A blood
- Pernicious anemia
- Family history without known genetic factors (first-degree relative with gastric cancer)
- Hereditary diffuse gastric cancer (*CDH1* mutation)
- Familial gastric cancer
- Hereditary nonpolyposis colon cancer
- Familial adenomatous polyposis
- Li-Fraumeni syndrome
- *BRCA1* and *BRAC2*
- Precursor lesions
 - Adenomatous gastric polyps
 - Chronic atrophic gastritis
 - Dysplasia
 - Intestinal metaplasia
 - Menetrier disease
- Ethnicity (in the United States, gastric cancer is more common among Asian/Pacific Islanders, Hispanics and African Americans)
- Obesity (the strength of this link is not clear)

PRETREATMENT STAGING

Tumor Markers

Most gastric cancers have at least one elevated tumor marker, but some benign gastric diseases show elevated serum tumor markers as well. Tumor markers in gastric cancer continue to have limited diagnostic usefulness, with their role more informative in follow-up after primary treatment. The most commonly used markers are serum carcinoembryonic antigen (CEA), cancer antigen (CA) 19-9, CA 50, and CA 72-4. There is wide variation in the reported serum levels of these markers; positive CEA and CA 19-9 levels varied from 8% to 58% and 4% to 65%, respectively. Overall, the sensitivity of each serum tumor marker alone as a diagnostic marker of gastric cancer is low. However, when the levels are elevated, it does usually correlate with stage of disease. Combining CEA with other markers, such as CA 19-9, CA 72-4, or CA 50, can increase sensitivity compared with CEA alone.⁵⁶⁻⁶²

In a large study evaluating serum CEA, α -fetoprotein, human chronic gonadotropin- β , CA 19-9, CA 125, as well as tissue staining for *HER2* in gastric cancer patients, only human chronic gonadotropin- β level >4 IU/L and a CA 125 level \geq 350 U/mL had prognostic significance. Elevated serum tumor marker levels in gastric cancer before chemotherapy may reflect not just tumor burden but also biology of disease.

Endoscopy

Endoscopy is the best method to diagnose gastric cancer as it visualizes the gastric mucosa and allows biopsy for a histologic diagnosis. Chromoendoscopy helps identify mucosal abnormalities through topical mucosal stains. Magnification endoscopy is used to magnify standard endoscopic fields by 1.5- to 150-fold. Narrow band imaging affords enhanced visualization of the mucosal microvasculature. Confocal laser endomicroscopy permits in vivo, three-dimensional microscopy including subsurface structures with diagnostic accuracy, sensitivity, and specificity of 97%, 90%, and 99.5%, respectively.⁶³⁻⁶⁵

Endoscopic ultrasound (EUS) is a tool for preoperative staging and selection for neoadjuvant therapy. It is used to assess the T and N stage of primary tumors. A study of 225 patients from MSKCC found that the concordance between EUS and pathology was lower than expected. The accuracy for individual T and N stage were 57% and 50%, respectively. However, the combined assessment of N stage and serosal invasion identified 77% of the patients at risk of disease-related death after curative resection.⁶⁶ Other investigators compared the accuracy of EUS with that of multidetector computed tomography (MDCT) and magnetic resonance imaging (MRI) and found that the overall accuracy was 65% to 92% (EUS), 77% to 89% (MDCT), and 71% to 83% (MRI) for T stage, and 55% to 66% (EUS), 32% to 77% (MDCT) for N stage, respectively. The corresponding sensitivity and specificity for serosal involvement were 78% to 100% (EUS), 83% to 100% (MDCT), and 89% to 93% (MRI) for T stage, and 68% to 100% (EUS), 80% to 97% (MDCT), and 91% to 100% (MRI) for N stage, respectively.^{65,67}

Computed Tomography

Once gastric cancer is suspected, a triphasic CT with oral and intravenous contrast of the abdomen, chest, and pelvis is imperative. In a study of 790 patients who underwent MDCT prior to surgery, the overall accuracy in determining T stage was 74% (T1 46%, T2 53%, T3 86%, and T4 86%), and for N staging it was 75% (N0 76%, N1 69%, and N2 80%). The sensitivity, specificity, and accuracy for lymph node metastasis were 86%, 76%, and 82%, respectively.⁶⁸ MDCT with thin-sliced multiplanar reconstruction (MPR) and water filling is increasingly used. The accuracy rate for advanced gastric cancer was 96% and for EGC it was 41%. An improvement on axial CT and MPR-MDCT was the addition of staging with three-dimensional MPR-MDCT. The detection rate for MPR with virtual gastroscopy was 98%. MPR-MDCT with combined water and air distention is superior to conventional axial imaging.⁶⁹

Magnetic Resonance Imaging

MRI is not used routinely in preoperative staging of gastric cancer. Several studies have demonstrated that CT and MRI are comparable in terms of accuracy and understaging.^{70,71} However, MRI is a useful modality to further characterize liver lesions identified on preoperative CT staging workup.

Positron Emission Tomography

Whole-body 2-[18F]-fluoro-2-deoxyglucose (FDG) positron emission tomography (PET) is being applied increasingly in the evaluation of gastrointestinal malignancies. In gastric cancer, approximately half of the primary tumors are FDG-negative; the diffuse (signet cell) subtype was most likely to be non-FDG avid, likely because of decreased expression of the glucose transporter-1 (Glut-1).⁷² In patients with non-FDG-avid primary tumor, FDG-PET/CT is not useful.⁷²⁻⁷⁶ PET/CT was tested as a tool to predict response to neoadjuvant chemotherapy. Ott et al.⁷⁷ reported 90% 2-year survival in patients with PET-defined response (<35% decrease standardized uptake value [SUV]) versus 25% for patients not responding to PET. PET response could be detected as early as 14 days. At least 60% of the patients were PET-nonresponding patients and thus could have been spared further chemotherapy. Authors of the MUNICON trial reported on patients who were PET nonresponders by day 14 after cisplatin and fluorouracil (5-FU) (CF) neoadjuvant chemotherapy, and subsequently were sent for surgery, and patients who were PET responders and continued 3 months of neoadjuvant therapy before surgery. The PET-responding patients had a survival benefit (hazard ratio [HR] = 2.13; $p < 0.15$). In PET-nonresponding patients, stopping the chemotherapy did not affect long-term survival.⁷⁸ Recent

studies, including one large meta-analysis, showed that in terms of diagnostic accuracy and lymph node staging EUS, MDCT, MRI, and PET/CT are comparable modalities. There were no significant differences between mean sensitivities and specificities.^{79,80} Even in patients whose tumors were FDG-avid, FDG-PET/CT scans did not identify occult peritoneal disease (0 of 18), but did identify extraperitoneal M1 disease in nine patients with bone ($n = 2$), liver ($n = 4$), and retroperitoneal lymph node ($n = 3$) involvement. In patients with FDG-avid tumors, PET may be useful in detecting metastatic disease and follow-up for recurrence. Interestingly, the presence of Glut-1- and FDG-avid gastric cancers may be associated with decreased OS.⁷² The role of PET/CT in the primary staging of gastric cancer remains to be established; its role might be better defined in advanced disease.

In a prospective study of 113 patients who were clinically staged as locally advanced but nonmetastatic gastric cancer (T3-T4, Nx or N+, M0), investigators found that FDG-PET/CT did identify occult metastatic disease in about 10% of patients. In this study, FDG-PET/CT did not identify occult peritoneal disease, suggesting a necessary role for laparoscopy in preoperative staging of locally advanced gastric cancer. A cost evaluation was also performed, and it suggested that if FDG-PET/CT is included as part of the staging algorithm, that would result in an estimated cost savings of approximately \$13,000 US dollars per patient.⁸¹

Staging Laparoscopy and Peritoneal Cytology

Staging laparoscopy with peritoneal lavage should be an integral part of the pretreatment staging evaluation of patients believed to have localized gastric cancer. Current noninvasive modalities used in preoperative staging of gastric cancer have sensitivities significantly lower than 100%, particularly in cases of low-volume peritoneal carcinomatosis.⁸²⁻⁸⁴ Current CT techniques cannot consistently identify low-volume macroscopic metastases that are ≤ 5 mm in size. Laparoscopy directly inspects the peritoneal and visceral surfaces for detection of CT-occult, small-volume metastases. Staging laparoscopy also allows for assessment of peritoneal cytology and laparoscopic ultrasound. Laparoscopic staging is done to spare nontherapeutic operations and for potential stratification in various trials.⁸⁵

The rate of detection of CT-occult M1 disease by laparoscopy depends on the quality of CT scanning and interpretation.⁸⁶ Muntean et al.⁸⁷ reported on 98 patients with primary gastric cancer: 45 underwent staging laparoscopy with subsequent surgery and 53 went directly to surgery. An unnecessary laparotomy was avoided in 38% of the patients. The overall sensitivity and specificity were 89% and 100%, respectively. Nonetheless, even high-quality MDCT is insufficiently sensitive for detection of low-volume extragastric disease and thus CT, EUS, and laparoscopy are complementary staging studies.^{88,89}

The value of peritoneal cytology as a preoperative staging tool in patients with gastric cancer who are potential candidates for curative resection by EUS and CT has been examined by several investigators. Bentrem et al.⁹⁰ reported on 371 patients who underwent R0 resection, 6.5% of whom had positive cytology after staging laparoscopy. Median survival of patients with positive cytology was 14.8 versus 98.5 months for patients with negative cytology findings ($p < 0.001$). Positive cytology predicted death from gastric cancer (relative risk = 2.7; $p < 0.001$) and is tantamount to M1 disease. Several groups confirmed these findings and concluded that staging laparoscopy with peritoneal cytology can change the management of gastric cancer in 6.5% to 52% of patients.^{83,91-94}

Laparoscopy can be performed as a separate staging procedure prior to definitive treatment planning or immediately prior to planned laparotomy for gastrectomy. When performed as a separate procedure, laparoscopy has the disadvantage of the additional risks and expense of a second general anesthetic. However,

separate procedure laparoscopy allows the additional staging information including cytology acquired at laparoscopy to be reviewed and discussed with the patient and in multidisciplinary treatment group prior to definitive treatment planning. Laparoscopic ultrasound (LUS) and “extended laparoscopy” are techniques that may increase the diagnostic yield of laparoscopy. Preliminary results reveal conflicting data on the added benefit of LUS and extended laparoscopy.⁹⁵⁻⁹⁷ Further prospective studies will be required to evaluate the cost-benefit relationship of LUS and extended laparoscopy in the routine or selective workup of patients with gastric cancer.

Although laparoscopic staging is thought to detect CT-occult metastatic disease in approximately 40% of patients and spares nontherapeutic operations in approximately one-third of patients with gastric cancer, one needs to remember that tumor biology, not staging, will eventually guide outcomes. Clearly, not all patients benefit from preoperative laparoscopic staging; therefore, future studies should address the issue of selective laparoscopy based on noninvasive staging (i.e., patients with T1 tumors). Staging laparoscopy with or without cytology should be considered only if therapy will be altered consequent to information obtained by laparoscopy.⁸²

STAGING, CLASSIFICATION, AND PROGNOSIS

For patients with surgically treated gastric adenocarcinoma, both pathologic staging (American Joint Committee on Cancer [AJCC]/International Union Against Cancer [UICC] or Japanese system) and classification of the completeness of resection (R classification) should be done. Although not formal components of the stage grouping, the AJCC recommends collection of additional prognostic factors: tumor location, serum CEA and CA 19.9, and histopathologic grade and type.⁹⁸

American Joint Committee on Cancer/ International Union Against Cancer Tumor, Node, Metastasis Staging

The AJCC/UICC TNM staging system for gastric cancer is outlined in Table 46.2.⁹⁸ The AJCC/UICC stage-stratified survival rates of 10,601 patients treated by surgical resection from the Surveillance, Epidemiology, and End Results program 1973 to 2005 public-use file diagnosed in years 1991 to 2000 are shown in Fig. 46.2. Several definitions in the most recent version of the AJCC (2010) differ from the previous version (2002). Tumors arising at the EGJ including Siewert type I or arising in the stomach ≤ 5 cm from the EGJ and crossing into the EJJ including Siewert types II and III are staged using the TNM system for esophageal adenocarcinoma. Gastric tumors lying ≤ 5 cm from the EGJ but that do not cross the EGJ into the esophagus are staged as gastric cancer.⁹⁸

In the AJCC/UICC staging system, tumor (T) stage is determined by depth of tumor invasion into the gastric wall and extension into adjacent structures (Fig. 46.3). The relationship between T stage, the overall stage, and survival is well defined (see Fig. 46.2). Nodal stage (N) is based on the number of involved lymph nodes, a criterion that may predict outcome more accurately than the location of involved lymph nodes.^{99,100} Tumors with 1 to 2 involved nodes are classified as pN1, 3 to 6 involved nodes are classified as pN2, and those with 7 or more involved nodes are classified as pN3 (N3a has 7 to 15 nodes and N3b has ≥ 16 nodes). The use of numerical thresholds for nodal classification has gained increasing acceptance, although the extent of lymphadenectomy and rigor of pathologic assessment may affect results.^{101,102} The nodal numerical threshold approach is based on observations that

survival decreases as the number of metastatic lymph nodes increases,^{103,104} and that survival significantly decreases at three or more involved¹⁰³ lymph nodes and again at seven or more involved lymph nodes.^{30,105}

Given the reliance on numerical thresholds for nodal staging, it is extremely important that adequate number of lymph nodes are retrieved surgically and examined pathologically. However, recent reports document poor compliance with AJCC staging primarily

because the number of lymph nodes removed and/or examined (≤ 15) was insufficient.^{104,106} Positive peritoneal cytology is classified as M1. Ratio-based lymph node classification (number of positive nodes over number of total nodes resected and evaluated) is an alternative to the threshold-based system currently utilized by the AJCC/UICC staging systems. It may minimize the confounding effects of regional variations in the extent of lymphadenectomy and pathologic evaluation on lymph node staging and thereby

Figure 46.3 Definition of American Joint Committee on Cancer/International Union Against Cancer T stage based on depth of penetration of the gastric wall.

reduce stage migration.¹⁰⁷⁻¹⁰⁹ Sun et al.¹⁰⁸ evaluated the ratio between metastatic and examined lymph nodes (RML) in a group of 2,159 patients who underwent curative gastrectomy. The anatomic location, number of positive lymph nodes (AJCC/UICC), and RML were analyzed for staging accuracy and relationship to survival. RML was an independent prognostic factor for survival and reduced stage migration. These findings were confirmed by several investigators reporting on approximately 2,000 patients treated by R0 gastrectomy.^{107,109-112}

Japanese Staging System

The most recent *Japanese Classification for Gastric Carcinoma* was published in 1998.¹¹³⁻¹¹⁶ The Japanese classification and staging system is more detailed than the AJCC/UICC staging system and places more emphasis on the distinction between clinical, surgical, pathologic, and “final” staging (prefixes “c,” “s,” “p,” and “f,” respectively). For example, a surgically treated and staged patient with locally advanced, nonmetastatic gastric cancer might be staged as pT3, pN2, sH0, sM0, stage f-IIIb (where H0 denotes no hepatic metastases and the “f” prefix denotes final clinicopathologic stage). The Japanese classification system also includes a classification system for EGC (Fig. 46.4).

In the combined superficial types, the type occupying the largest area should be described first, followed by the next type (e.g., IIc + III). Type 0I and type 0IIa are distinguished as follows: type 0I, the lesion has a thickness of more than twice that of the normal mucosa; type 0IIa, the lesion has a thickness up to twice that of the normal mucosa.

Similar to the AJCC/UICC staging system, primary tumor (T) stage in the Japanese system is based on the depth of invasion and extension to adjacent structures, as outlined in Table 46.3.¹¹⁷ However, the assignment of lymph node (N) stage involves much more rigorous pathologic assessment than is required for AJCC/UICC staging. The Japanese system extensively classifies 18 lymph node regions into four N categories (N0 to N3) depending on their relationship to the primary tumor and anatomic location.¹¹⁸ Most perigastric lymph nodes (nodal stations 1 through 6) are considered group N1. Lymph nodes situated along the proximal left gastric artery (station 7), common hepatic artery (station 8), celiac axis (station 9), splenic artery (station 11), and proper hepatic artery (station 12) are defined as group N2. Para-aortic lymph nodes (station 16) are defined as group N3. However, some lymph nodes, even perigastric nodes for specific tumor locations, can be regarded as M1 disease (i.e., involvement of station 2 in the case of antral tumors). This is because their involvement in antral tumors is rare and portrays a poor prognosis.¹¹⁷

Figure 46.4 Japanese classification system for early gastric cancer.

TABLE 46.3

Japanese Gastric Cancer Association Staging System

Tumor Stage				
T1	Tumor invasion of mucosa and/or muscularis mucosa or submucosa			
T2	Tumor invasion of muscularis propria or subserosa			
T3	Tumor penetration of serosal			
T4	Tumor invasion of adjacent structures			
TX	Unknown			
Nodal Stage				
N0	No evidence of lymph node metastasis			
N1	Metastasis to group 1 lymph nodes, but no metastasis to groups 2 to 3 lymph nodes			
N2	Metastasis to group 2 lymph nodes, but no metastasis to group 3 lymph nodes			
N3	Metastasis to group 3 lymph nodes			
NX	Unknown			
Hepatic Metastasis Stage (H)				
H0	No liver metastasis			
H1	Liver metastasis			
HX	Unknown			
Peritoneal Metastasis Stage (P)				
P0	No peritoneal metastasis			
P1	Peritoneal metastasis			
PX	Unknown			
Peritoneal Cytology Stage (CY)				
CY0	Benign/indeterminate cells on peritoneal cytology ^a			
CY1	Cancer cells on peritoneal cytology			
CYX	Peritoneal cytology was not performed			
Other Distant Metastasis (M)				
M0	No other distant metastases (although peritoneal, liver, or cytologic metastases may be present)			
M1	Distant metastases other than the peritoneal, liver, or cytologic metastases			
MX	Unknown			
Stage Grouping

^a Cytology believed to be “suspicious for malignancy” should be classified as CY0. Adapted from Japanese Gastric Cancer Association. Japanese Classification of Gastric Carcinoma - 2nd English Edition. *Gastric Cancer* 1998;1:10.

The Japanese staging system also includes elements not included in the AJCC/UICC system (see Table 46.3). These are macroscopic descriptions of the tumor (EGC subtype or Borrmann type for more advanced tumors), extent of peritoneal metastases (classified as P0-1), extent of hepatic metastases (H0-1), and peritoneal cytology findings (CY0-1). Recent comparison of the

Japanese and AJCC/UICC staging systems in 731 patients suggests that both are comparable.¹¹⁹ However, older studies suggest that the AJCC/UICC system more accurately estimates prognosis.¹⁰¹

Classification of Esophagogastric Junction Cancers

EGJ cancers (i.e., tumors with a definitive component involving the EGJ) are no longer classified by the AJCC as gastric cancers per se. They are briefly reviewed here for historical reasons. Siewert and Stein¹²⁰ classified adenocarcinomas of the EGJ (Siewert classification) into three distinct clinical entities that arise within 5 cm of the EGJ: type I arises in the distal esophagus and may infiltrate the EGJ from above, type II arises in the cardia or the EGJ, and type III arises in the subcardial stomach and may infiltrate the EGJ from below. The assignment of tumors to one of these subtypes is based on morphology and the anatomic location of the epicenter of the tumor. The Siewert classification has important therapeutic implications.¹²¹ The lymphatic drainage routes differ for type I versus types II and III lesions. The lymphatic pathways from the lower esophagus pass both cephalad and caudad. In contrast, the lymphatic drainage from the cardia and subcardial regions is caudad. Thus, the Siewert classification provides a practical means for choosing among surgical options. For type I tumors, esophagectomy is required, whereas types II and III tumors can be treated by transabdominal gastrectomy.^{121,122}

Resection Classification

The R classification system indicates the amount of residual disease left after tumor resection.¹²³ R0 indicates no gross or microscopic residual disease, R1 indicates microscopic residual disease (positive margins), and R2 signifies gross residual disease. The R classification has implications for individual patient care and clinical research. Results of clinical trials that include surgery should include information on R status. Readers should be aware of the dual use of the “R” terminology in the gastric cancer literature. Prior to 1995, the Japanese staging and treatment vernacular included an “R level,” which described the extent of lymphadenectomy. The latter is now classified by “D” (for dissection) level.

GASTRIC CANCER NOMOGRAMS: PREDICTING INDIVIDUAL PATIENT PROGNOSIS AFTER POTENTIALLY CURATIVE RESECTION

Kattan et al.¹⁰³ have developed a nomogram for predicting individual patient 5-year disease-specific survival using established prognostic factors derived from a population of 1,039 patients with gastric cancer treated by R0 surgical resection without neoadjuvant therapy at a single institution (nomograms@mskcc.org). Clinicopathologic factors incorporated in the nomogram include age and gender, primary tumor site, Laurén classification, numbers of positive and negative lymph nodes resected, and depth of invasion. This nomogram was subsequently validated by several authors. Peeters et al.¹²⁴ found that the nomogram prognosticates better than the AJCC staging system. Novotny et al.¹²⁵ validated the nomogram in 862 patients from Germany and the Netherlands; Strong et al.¹²⁶ compared outcomes using the nomogram in 711 patients from the United States and 1,646 patients from Korea. This tool may be useful for individual patient counseling regarding the use of adjuvant therapy, follow-up scheduling, and clinical trial eligibility assessment, and is available for personal handheld computer devices at www.nomograms.org.

Recently, a large retrospective cohort study of 1,273 patients who underwent resection revealed that having a positive family

history of gastric cancer (defined as a self-reported history of cancer in first-degree relatives) was associated with significant reduction in disease-free survival (DFS; $p = 0.012$), relapse-free survival ($p = 0.006$), and OS ($p = 0.005$) when compared with those who did not have a family history of gastric cancer. The improvement in outcomes was more pronounced among patients with stage III or IV gastric cancer, with significant adjusted HRs for DFS (HR = 0.49; 95% confidence interval [CI] = 0.29 to 0.84), relapse-free survival (HR = 0.47; 95% CI = 0.30 to 0.87), and OS (HR = 0.47; 95% CI = 0.26 to 0.84), respectively.¹²⁷

TREATMENT OF LOCALIZED DISEASE

Stage I Disease (Early Gastric Cancer)

Classification of Early Gastric Cancer and Risk for Nodal Metastases

The Japanese Research Society for Gastric Cancer has classified EGCs based on endoscopic criteria first established for the description of T1 tumors. The current classification system is used for both in situ and invasive tumors and categorizes tumors based on endoscopic findings as follows: protruded, type 0I; superficial elevated, type 0IIa; flat, type 0IIb; superficial depressed, type 0IIc; and excavated, type 0III (see Fig. 46.4). The English language version of the Japanese EGC classification contains excellent color photos of these subtypes.¹²⁸ This classification system is important in describing patients treated by newer gastric-sparing approaches for EGC, such as endoscopic mucosal resection (EMR).^{114–116,129} The risk for lymph node metastasis is important when evaluating treatment options for patients with EGC. The frequency and anatomic distribution of nodal disease are related to the depth of tumor invasion. In a Japanese series of >5,000 patients who underwent gastrectomy with lymph node dissection for EGC, none of the 1,230 patients with well-differentiated intramucosal tumors <3 cm in diameter (regardless of ulceration) had lymph node metastases.¹³⁰ None of the 929 patients with EGC without ulceration had nodal metastases, irrespective of tumor size. In contrast, in the subset of >2,000 patients with tumors that invaded the submucosa, the frequencies of lymph node involvement for tumors ≤1.0 cm, 1.1 to 2.0 cm, 2.1 to 3.0 cm, and >3.0 cm were 7.9%, 13.3%, 15.6%, and 23.3%, respectively. Thus, once tumors penetrate into the submucosa, the risk for nodal metastasis increases with tumor size.^{131–137} The estimates of the frequency of nodal disease in EGC are based on conventional light-microscopic histologic assessment. However, the use of more sensitive techniques such as serial sectioning of individual lymph nodes, immunohistochemistry, or reverse transcriptase-polymerase chain reaction may increase the frequency of detection of occult micrometastatic disease.¹³⁸ The clinical significance of micrometastasis remains unknown.

Endoscopic Mucosal Resection

A subset of patients with EGC can undergo an R0 resection without lymphadenectomy or gastrectomy. The Japanese have popularized EMR for EGC. This approach involves the submucosal injection of fluid to elevate the lesion and facilitate complete mucosal resection under endoscopic guidance. Most centers reporting significant experience with EMR are in Japan. There is less experience with EMR in Western countries. Only patients with tumors that have extremely low metastatic potential should be offered EMR. These are generally well-differentiated, superficial type IIa or IIc lesions, <3 cm in diameter, and located in an easily manipulated area. Tumors invading the submucosa are at increased risk for metastasizing to lymph nodes and are not usually considered candidates for EMR.

Recently, Bennett et al.¹³⁹ reviewed the available data reporting on EMR for EGC. No randomized controlled trial (RCT) reported

on EMR. The indications for EMR are well-differentiated lesions, size ≤ 20 mm in elevated type, ≤ 10 mm in depressed type, no ulceration, and limited to the mucosa.¹⁴⁰ The incidence of lymph node metastases for such lesions is approximately 1%. Complete resection of selected EGCs can be accomplished in a majority of cases (73.4% to 98%).^{139,141,142}

Two retrospective reports indicated that EMR can reduce the risk of local residual tumor, and repeat EMR is an effective option.^{143,144} Recurrence after EMR varies with type of EGC. Ida et al.¹⁴⁵ reported on 412 patients: 8 of 199 (4.0%) had recurrence of lesions size 20 to 40 mm; 5 patients were retreated by EMR and 3 underwent open surgery; and none had lymph node metastases. Patients (0/305) with lesions ≤ 20 mm did not have recurrence. Complication rates associated with EMR are low. Bleeding and perforation are reported in 0% to 20.5% and 0% to 5.2% of patients, respectively.^{141,146-149} The reported morbidity and mortality rates in patients undergoing open surgery ($n = 256$) versus EMR ($n = 56$) were 0.8% and 7.8% versus 0% and 16%, respectively.^{139,150}

Fukase et al.^{151,152} reported on the long-term outcomes of patients undergoing open surgery ($n = 116$) versus EMR ($n = 59$). For patients age 65 year or under, the 5- and 10-year survival rates were 100% and 91.7% versus 92.8% and 92.8%, with open surgery and EMR, respectively. For patients older than 65 years of age, the 5- and 10-year survival rates were 100% and 75% versus 80.8% and 80.8%, respectively. The differences were not statistically significant. Similar results were reported by Park et al.¹⁵³ and Kim et al.¹⁵⁴

There are emerging variations of EMR techniques, including the cap suction and cut versus a ligating device. As outcome studies accumulate demonstrating favorable survival, EMR is emerging as the definitive management of selected EGCs and is not just reserved for patients in whom gastrectomy cannot be considered. However, RCTs are needed to establish an outcome advantage over open surgery.^{140,155-165}

Limited Surgical Resection

Given the low rate of nodal involvement for patients with EGC, limited resection may be a reasonable alternative to gastrectomy for some patients. There are no well-accepted pretreatment criteria for selection of patients for limited resection. Based on available pathology studies, patients with small (< 3 cm) intramucosal tumors and those with nonulcerated intramucosal tumors of any size may be candidates for EMR or limited resection. Surgical options for these patients may include gastrotomy with local excision. This procedure should be performed with full-thickness mural excision (to allow accurate pathologic assessment of T status) and is often aided by intraoperative gastroscopy for tumor localization. Formal lymph node dissection is not required in these patients.

Gastrectomy

Gastrectomy with lymph node dissection should be considered for patients with EGC who cannot be treated with EMR or limited surgical resection, and/or patients who have intramucosal tumors with poor histologic differentiation, or size > 3 cm, or who have tumor penetration into the submucosa or beyond. Gastrectomy with lymph node dissection allows for adequate pathologic staging and local therapy for these patients at increased risk of nodal metastasis. Dissection of level I lymph nodes is a reasonable minimum standard at this time for higher risk EGCs. The roles for nodal "sampling" without formal node dissection (D0 dissection) and sentinel lymph node (SLN) mapping and biopsy in the treatment of EGC remain undefined at this time.

Stage II and Stage III Disease

Surgery

Surgical resection of the primary tumor and regional lymph nodes is the cornerstone of treatment for patients with localized gastric

cancer. However, for stage II and III disease, surgery is necessary but often not sufficient for cure. The general therapeutic goal is to achieve a microscopically complete resection (R0). A complete discussion of all the technical details of gastric resection and reconstruction is beyond the scope of this chapter. However, specific surgical issues of oncologic significance are addressed here, including the extent of gastrectomy, extent of regional lymph node dissection, and role of partial pancreatectomy and splenectomy. Additional technical details can be found in surgical atlases and the section "Technical Treatment-Related Issues."

Extent of Resection for Mid- and Distal Gastric Cancers.

The extent of gastrectomy required for satisfactory primary tumor treatment depends primarily on the gross and microscopic status of surgical margins. For most clinical situations, a 5-cm negative margin around the tumor and microscopically negative surgical margin (R0) are the treatment goals. When gastrectomy is performed with curative intent, frozen-section assessment of proximal and distal resection margins should be used intraoperatively to improve the likelihood that an R0 resection has been attained. Three relatively small prospective RCTs have compared total gastrectomy with partial (subtotal) gastrectomy for distal gastric cancer.¹⁶⁶⁻¹⁶⁸ Overall morbidity, mortality, and oncologic outcome were comparable in each of these RCTs. When the general oncologic goal of an R0 resection can be achieved by a gastric-preserving approach, partial gastrectomy is preferred over total gastrectomy. This is particularly relevant for distal gastric cancers, for which a gastric-preserving R0 approach may minimize the risks of specific sequelae of total gastrectomy such as early satiety, weight loss, and the need for vitamin B₁₂ supplementation.

Extent of Resection for Proximal Gastric Cancer.

There are many choices for surgical management of adenocarcinomas arising at the EGJ or in the proximal stomach (Siewert types II and III). Many abdominal surgeons have advocated transabdominal approaches with resection of the lower esophagus and proximal stomach or total gastrectomy. Surgeons trained in thoracic surgery have frequently advocated a combined abdominal and thoracic procedure (often termed *esophagogastrectomy*) with an intrathoracic or cervical anastomosis between the proximal esophagus and the distal stomach, or a procedure termed *transhiatal (or blunt) esophagectomy* (THE), which involves resection of the esophagus and EGJ with mediastinal dissection performed in a blunt fashion through the esophageal hiatus of the diaphragm. When THE is performed for adenocarcinoma of the EGJ, gastrointestinal continuity is restored by low cervical anastomosis of the stomach (usually advanced through the esophageal bed in the posterior mediastinum) to the cervical esophagus. Selection among the options has been dependent primarily on individual surgeon training and experience.

The optimal surgical procedure for patients with localized tumors of the EGJ and proximal stomach is a matter of considerable debate. A recently completed Dutch RCT compared transthoracic esophagogastrectomy (TTEG, with abdominal and thoracic incisions) with THE in 220 patients with adenocarcinoma of the esophagus and EGJ.¹⁶⁹ Although this trial was designed for patients with esophageal cancer, 40 (18%) of the patients had adenocarcinomas of the EGJ (Siewert type II), and the operations evaluated are among those considered for patients with Siewert type II or III cancers. Perioperative morbidity was higher after THE, but there was no significant difference in in-hospital mortality compared with TTEG. Although median overall, disease-free, and quality-adjusted survival did not differ significantly between the groups, there was a trend toward improved OS at 5 years with TTEG. These results are judged equivocal, and there is currently no consensus on the optimal surgical approach for patients with Siewert type II tumors.¹⁷⁰ Until longer follow-up of the Dutch trial is available and/or additional RCTs are performed, the surgical approach to these patients will continue to be individualized and determined

by a constellation of factors including surgeon factors (training and experience), patient factors (age, comorbid conditions, and functional status), and tumor factors (pretreatment T and N stage).

Extent of Lymphadenectomy. There has been intense debate surrounding the extent of lymphadenectomy. It involves at least two important issues: (1) adequate staging in terms of the number of lymph nodes resected surgically and examined pathologically, and (2) adequate therapy (i.e., do some forms of lymphadenectomy result in better outcomes?).^{171–182}

Single-institution reports suggest that the number of pathologically positive lymph nodes is of prognostic significance,^{100,102,150,153–185} and that removal and pathologic analysis of at least 15 lymph nodes is required for adequate pathologic staging.^{99,186} Indeed, the current AJCC staging system accounts for these issues and therefore requires analysis of ≥ 16 lymph nodes to assign a pathologic N stage.¹⁸⁷ The possible therapeutic benefit of extended lymph node dissection D2 versus D1 dissection has been the focus of six RCTs, which are summarized in Table 46.4.^{167,188–193} These trials were performed because retrospective and prospective nonrandomized evidence suggested that extended lymph node dissection may be associated with improved long-term survival.¹⁹⁴ The RCTs tested the hypothesis that removal of additional pathologically positive lymph nodes (not generally removed as part of a standard lymph node dissection) improves survival. The larger RCTs attempted to follow what are referred to as the “Japanese rules” for lymph node classification and dissection that govern the extent of nodal dissection required based on anatomic location of the primary tumor.¹⁹⁵ Using these Japanese definitions, the RCTs compared limited lymphadenectomy of the perigastric lymph nodes (D1 dissection) to en bloc removal of second-echelon lymph nodes (D2 dissection). At least two of the completed trials are underpowered for their primary end point, OS.^{167,188} The trials from the Medical Research Council (MRC) of the United Kingdom¹⁸⁹ and the Dutch Gastric Cancer Group¹⁹⁰ have received the most attention and discussion.

The MRC trial registered 737 patients with gastric adenocarcinoma; 337 (46%) patients were ineligible by staging laparotomy because of advanced disease, and 400 (54%) patients were randomized at the time of laparotomy to undergo D1 (200) or D2 (200) lymph node dissection. Postoperative morbidity was significantly greater in the D2 group (46% versus 28%; $p < 0.001$), and in-hospital mortality rates were also significantly higher in the D2 group than in the D1 group (13% versus 6%, $p < 0.04$).¹⁸⁹ The most frequent postoperative complications were related to anastomotic leakage (D2 26% versus D1 11%), cardiac complications (8% versus 2%), and respiratory complications (8% versus 5%). The excess morbidity and mortality seen in the D2 group were thought to be related to the routine use of distal (left) pancreatectomy and splenectomy. Partial pancreatectomy and splenectomy were performed to maximize clearance of lymph nodes at the splenic hilum, primarily for patients with proximal tumors; however, many surgeons now believe that adequate lymph node dissection can be performed with pancreas- and spleen-preserving techniques. Long-term follow-up analysis of patients in the MRC trial demonstrated comparable 5-year OS rates of 35% and 33% in the D1 and D2 dissection groups, respectively. Survival based on death from gastric cancer as the event was also similar in the D1 and D2 groups (HR = 1.05; 95% CI = 0.79 to 1.39), as was recurrence-free survival (HR = 1.03; 95% CI = 0.82 to 1.29). The authors concluded that classic Japanese-style D2 lymphadenectomy (with partial pancreatectomy and splenectomy) offered no survival advantage over D1 lymphadenectomy.

The Dutch Gastric Cancer Group conducted a larger RCT with optimal surgical quality control comparing D1 to D2 lymph node dissection for patients with gastric adenocarcinoma that was updated in 2010 after 15-year follow-up.¹⁹⁶ Between 1989 and July 1993, 1,078 patients were entered, of whom 996 patients were eligible; 711 patients were randomized to D1 dissection ($n = 380$) or

D2 dissection ($n = 331$). To maximize surgical quality control, all operations were monitored.¹⁹⁷ Initially, this oversight was done by a Japanese surgeon who trained a group of Dutch surgeons, who in turn acted as supervisors during surgery at 80 participating centers. Notwithstanding the extraordinary efforts to ensure quality control of the two types of lymph node dissection, both noncompliance (not removing all lymph node stations) and contamination (removing more than was indicated) occurred, thus blurring the distinction between the two operations and confounding the interpretation of the oncologic end points.^{196,198} The postoperative morbidity rate was higher in the D2 group (43% versus 25%; $p < 0.001$), the reoperation rate was also higher at 18% (59/331) versus 8% (30/380), and the mortality rate was also significantly higher in the D2 group (10% versus 4%; $p = 0.004$). Patients treated with D2 dissection also required a longer hospitalization.¹⁹⁹ As in the MRC trial, partial pancreatectomy and splenectomy were performed en passant in the D2 group. Five-year survival rates were similar in the two groups: 45% for the D1 group and 47% for the D2 group (95% CI for the difference = -9.6% to 5.6%). The subset of patients who had R0 resections, excluding those who died postoperatively, had cumulative risks of relapse at 5 years of 43% with D1 dissection and 37% with D2 dissection (95% CI for the difference = -2.4% to 14.4%).

The Dutch investigators concluded that there was no role for the routine use of D2 lymph node dissection in patients with gastric cancer. At 15-year follow-up, 174/711 (25%) patients were alive, all but one without recurrence. The OS was 21% (82/711) and 29% (92 patients) for the D1 and D2 groups, respectively ($p = 0.34$). Interestingly, gastric cancer-specific death was higher in the D1 group 48% (182/380) versus 37% (123/331). Local recurrence was higher in the D1 group 22% (82/380) versus 12% (40/331), and regional recurrence 19% (73/380) versus 13% (43/331). The authors concluded that after 15 years of follow-up, D2 lymphadenectomy is associated with lower locoregional recurrence and gastric cancer-specific death rates than D1 lymphadenectomy. D2 resection is also associated with higher postoperative mortality, morbidity, and reoperation rates. Examining the results after 15-year follow-up and given the data regarding gastric cancer-specific mortality, local recurrence, and regional recurrence, the authors revised their original conclusion: “Because spleen-preserving D2 resection is safer in high-volume centers, it is the recommended surgical approach for patients with potentially curable gastric cancer.”¹⁹⁶

Dejiuli et al.¹⁹¹ reported on the Italian Gastric Cancer Study Group experience with a prospective randomized trial comparing pancreas-sparing D1 versus D2. There were 76 patients randomized to undergo D1 and 86 D2 resections. Complication rates were higher in the D2 group: 16.3% versus 10.5%. Postoperative mortality was higher in the D1 group: 1.3% versus 0% in the D2 group. Thus far, no survival data are available. The authors concluded that, in experienced hands, the morbidity and mortality can be as low as shown by Japanese surgeons.

Wu et al.¹⁹² reported on a randomized trial comparing D1 versus D3 dissections.¹⁹⁹ There were no operative deaths, and morbidity was only 12%. At median follow-up of 94.5 months, D3 showed better overall 5-year survival of 59.5% (95% CI = 50.3 to 68.7) versus 53.6% (95% CI = 44.2 to 63.0; $p = 0.041$), and a trend toward better DFS at 5 years: 40.3% versus 50.6% ($p = 0.197$). Only 13% had pancreas or splenic resection as compared with 23% in the Dutch trial. The authors concluded that D3 as compared to D1 offers survival benefit. As far as the authors of this chapter understand, this is the first RCT to demonstrate survival advantage for more extensive lymphadenectomy (D3). As such, it requires careful examination. Roggin and Posner²⁰⁰ have critically reviewed the work by Wu et al.¹⁹² One controversial element of this trial was the use of OS versus gastric cancer-specific survival; 17/111 (15%) of the reported deaths were not related to tumor recurrence, resulting in very small survival benefit.

Interpretation of the existing level 1 evidence is encumbered by a number of issues that have been discussed in detail elsewhere.^{171,172} The primary concerns relate to whether (1) the increased operative

mortality associated with protocol-mandated partial pancreatectomy and splenectomy for patients with proximal tumors undergoing D2 dissection prevented identification of a potential therapeutic impact of extended lymph node dissection, and (2) the phenomena of noncompliance and contamination led to homogenization of the operative procedures to such an extent that the fundamental hypothesis was not tested. Owing to these interpretation issues, the question of a possible therapeutic benefit of D2 dissection remains unsettled.

Many Japanese gastric surgeons have considered the caveats associated with the MRC and Dutch trials and believe that, notwithstanding inherent patient selection and stage migration biases,^{171,196,198,201,202} the existing retrospective data provide sufficient proof of a clinical benefit of D2 dissection. On this basis, D2 dissection has been adopted as the standard of care for patients with localized, higher-risk gastric cancer in many centers in Japan and some specialized centers in the West.²⁰³ The Japanese Clinical Oncology Group (JCOG-9501) has investigated an even more aggressive surgical approach in an RCT evaluating standard D2 versus D2-plus (para-aortic node dissection [PAND]) in the management of completely resected (R0) T2–4 gastric cancer.^{204,205} Between July 1995 and April 2001, 523 patients from 25 institutions were registered. Patients were randomized intraoperatively to undergo D2 lymphadenectomy alone (263 patients) or D2 lymphadenectomy plus PAND (260 patients). The primary end point was OS. Postoperative morbidity was higher in the PAND group (28% versus 21%; $p = 0.07$), and mortality was similar at 0.8% in each group. Five-year OS for patients undergoing PAND was 70.3% versus 69.2% (HR = 1.03; $p = 0.85$). There was no significant difference in recurrence-free survival. The authors concluded that, as compared to D2 lymphadenectomy, PAND when added to D2 lymphadenectomy does not improve survival rates.

Another Japanese study compared D2 with extended PAND (D4).²⁰⁶ This trial randomized patients to undergo gastrectomy with D2 ($n = 135$) or D4 ($n = 134$) lymphadenectomy. The 5-year survival rates were 52.6% versus 55%, respectively ($p = 0.8$). The authors concluded that prophylactic D4 dissection is not recommended. In an RCT, a Western group from Poland investigated D2 dissection versus extended D2 dissection defined according to the Japanese Gastric Cancer Association classification.²⁰⁷ They randomized 275 patients with gastric cancer to gastrectomy with D2 ($n = 141$) versus D2 + lymphadenectomy ($n = 134$). The overall postoperative morbidity and mortality were similar and did not differ statistically. Survival data are not available at this time.²⁰⁷ Thus, the limits of radical surgery have been reached in Japan and the pendulum has swung back toward D2 dissection in clinical settings in which this can be safely performed.²⁰¹

In summary, lymph nodes should be considered as indicators that the gate was opened rather than as the gate keepers for cure.²⁰⁸ None of the prospective RCT trials executed in the West demonstrated survival advantage for more extensive lymphadenectomy. However, none of these studies were powered enough to detect single-digit difference in 5-year OS. Several non-a priori planned subgroup analyses were done and showed some survival advantage for certain subgroups. These analyses cannot be used to form evidence-based medicine, but should be used to form hypotheses for further RCT studies. In high-volume specialty centers, spleen- and pancreas-preserving D2 dissection is performed safely, and can potentially result in decreased gastric cancer-specific mortality based on 15 years of follow-up from the Dutch study (D2 37% versus 48%; $p = 0.01$).¹⁹⁶

A recently published RCT from the multicenter Italian Gastric Cancer Study Group compared D1 to D2 lymphadenectomy for gastric adenocarcinoma with primary outcome of OS over median follow-up of 8.8 years.²⁰⁹ There was no significant difference in OS (5-year OS = 66.5% versus 64.2%), operative morbidity (12% versus 17.9%), and mortality (3% versus 2.2%) in patients undergoing D1 and D2 gastrectomy; however, subgroup analysis suggested a trend toward improved disease-specific survival with

D2 gastrectomy in patients with advanced T-stage (pT2-4) and node-positive disease (5-year disease-specific survival: D1 versus D2 = 38% versus 59%; $p = 0.055$).

A systematic review and meta-analysis of eight RCTs encompassing over 2,000 patients (D1, $n = 1,042$; D2, $n = 1,002$) evaluated the safety and efficacy of extended lymphadenectomy in gastric cancer.²¹⁰ A significant increase in operative morbidity and mortality was evident in patients undergoing extended D2 lymphadenectomy, with a trend in decreased disease-specific mortality in those having spleen- and pancreas-preserving gastrectomy. Longer-term survival is required to ascertain oncologically relevant outcome benefit with D2 gastrectomy.

Partial Pancreatectomy and Splenectomy Resect or Preserve? Partial (left, distal) pancreatectomy and splenectomy have been performed as part of D2 lymph node dissection to remove the lymph nodes along the splenic artery (station 11) and lymph nodes within the splenic hilum (station 12), primarily for patients with tumors located in the proximal and midstomach. Indeed, partial pancreatectomy and splenectomy were required for patients with proximal tumors in the D2 arm of the Dutch and MRC RCTs but were required only for direct tumor extension in the D1 arm. In the Dutch and MRC D1 versus D2 randomized trials, splenectomy was associated with increased risk of surgical complications and operative mortality. In addition, a multivariate analysis suggested that splenectomy is associated with inferior long-term survival. The frequent performance of splenectomy (e.g., 30% of patients in the D2 arm versus 3% in the D1 arms of the Dutch trial) in the patient undergoing extended D2 lymphadenectomy, with its associated adverse effects on both short- and long-term mortality, confounds the interpretation of the Dutch and MRC RCTs. Thus, the hypothesis that spleen- and pancreas-preserving D2 lymph node dissection improves survival remains unproven. There is an evolving consensus that splenectomy should be performed only in cases with intraoperative evidence of direct tumor extension into the spleen, or its hilar vasculature, or when the primary tumor is located in the proximal stomach along the greater curvature.²¹¹ Partial pancreatectomy should be performed only in cases of direct tumor extension to the pancreas.

Recent reports have described pancreas- and spleen-preserving forms of D2 dissection.^{212–218} This organ-preserving modification of classic D2 dissection allows for dissection of some station 11 and 12 lymph nodes without the potential adverse effects of pancreatectomy and/or splenectomy. In a small single-institution RCT recently reported from Chile, Csendes et al.²¹⁹ randomized 187 patients with localized proximal gastric adenocarcinoma to treatment by total gastrectomy with D2 lymph node dissection plus splenectomy or total gastrectomy with D2 lymphadenectomy alone. Operative mortality was similar in both groups (splenectomy group, 3%; control group, 4%). However, septic complication rates were higher in the splenectomy arm than in the control arm ($p < 0.04$). There was no difference in 5-year OS between study groups, although it is not clear that the trial was designed with survival as the primary end point. Other investigators confirmed these findings.^{218,220,221}

The JCOG is conducting a multi-institutional RCT (JCOG 0110-MF) comparing D2 dissection with and without splenectomy for patients diagnosed with proximal gastric cancer.²²² The hypothesis to be tested is that 5-year OS of patients treated by extended D2 dissection *without* splenectomy is 5% less than that of patients treated by D2 dissection *with* splenectomy. With a planned accrual of 500 patients, this design will provide 70% power to reject the null hypothesis when 5-year OS is 3% greater following splenic preservation compared with splenectomy.²²² The results of this trial will better define the short- and long-term effects of splenectomy for patients with proximal gastric cancers undergoing extended lymphadenectomy.

In an effort to reduce operative morbidity and mortality without compromising oncologic outcome in patients undergoing

extended lymphadenectomy for gastric adenocarcinoma, eight clinical trials have compared laparoscopic to open gastrectomy with D2 lymph node dissection. A meta-analysis was conducted of these eight trials, which enrolled nearly 1,500 patients with gastric cancer to assess the feasibility and safety of laparoscopic total gastrectomy with D2 lymphadenectomy compared to the same operation done in the standard open manner.²²³ The laparoscopic technique was associated with significantly longer operative time, less operative blood loss, fewer analgesic requirements, earlier return of bowel function, shorter hospital stay, and reduced operative morbidity (relative risk = 0.70; 95% CI = 0.50 to 0.98; $p = 0.035$). The total number of lymph nodes removed surgically and analyzed pathologically as well as operative mortality was not significantly different between groups. Further well-designed clinical RCTs are warranted to define the role of laparoscopic gastrectomy and extended lymphadenectomy for gastric adenocarcinoma. (A more detailed discussion follows in the section titled “Minimally Invasive Surgery for Gastric Resection.”)

Laparoscopy clearly has a role in the complete staging of disease in patients with gastric adenocarcinoma and the detection of radiologically occult macroscopic, or microscopic peritoneal cytology positive-only metastasis. Laparoscopy and peritoneal cytology are important for accurate staging and the detection of occult metastatic disease. This methodology adds value to modern imaging techniques, for positive microscopic peritoneal cytology-only disease is tantamount to macroscopic M1 disease in terms of oncologic outcome.

A recent international multidisciplinary expert panel created statements to define processes of care relevant to the perioperative management of patient with gastric cancer.²²⁴ Ten processes were deemed essential to maintaining quality of care:

1. CT of the abdomen and pelvis is part of preoperative staging.
2. PET scans are not routinely indicated.
3. Adjuvant therapy should be considered.
4. Clinical trials should be conducted and patients considered for participation.
5. Treatment decision making should involve a multidisciplinary team.
6. Hospitals must have sufficient systems in place to support the care of patients with gastric cancer.
7. Sixteen or more lymph nodes should be resected and staged pathologically.
8. Surgery should only be performed to palliate major symptoms in the setting of metastatic disease.
9. Surgeons experienced in the treatment of gastric cancer should be performing the operations.
10. These surgeons should also have advanced laparoscopic surgery experience for laparoscopic gastric resection.

These processes were deemed to be of indeterminate necessity for maintaining quality of care:

1. Diagnostic laparoscopy before treatment
2. Multidisciplinary approach to patients with linitis plastica
3. Genetic testing for diffuse gastric cancer, family history, or age <45 years at time of diagnosis
4. Endoscopic removal of select T1aNO lesions
5. D2 lymphadenectomy in curative intent cases
6. D1 lymphadenectomy for EGC or patients with comorbidities
7. Frozen section analysis of gastric resection margins
8. Nonemergent cases performed in a hospital with a volume of >15 gastric cancer resections per year
9. By a surgeon who performs more than six gastric resections per year

Individualized Assessments of Lymph Node Involvement.

Recent attention has focused on methods of individual assessment of risk of lymphatic spread. These techniques offer the possibility of tailoring surgical therapy for an individual patient based on clinico-

pathologic risk assessment of the primary tumor and/or preoperative or intraoperative identification of SLNs, or primary draining lymph nodes. At present, at least three approaches to individual nodal risk assessment have been evaluated: computer modeling, preoperative endoscopic peritumoral injection, and SLN biopsy.

Preoperative Computer Modeling of Individual Patient Nodal Involvement. Kampschoer et al.²²⁵ have developed a computer program to estimate the probability of spread to specific nodal regions for an individual patient using his or her pretreatment clinicopathologic data. The program incorporated data on tumor size, depth of infiltration, primary tumor location, grade, type, and macroscopic appearance of primary tumors from 2,000 patients with surgically resected gastric cancers treated at the National Cancer Center of Tokyo. The data set used for matching individual patient data is continuously updated and now includes >8,000 patients. This computer model has been validated in non-Japanese patients in Germany²²⁶ and Italy.²²⁷ In the United States, Hundahl et al.²²⁸ retrospectively applied this computer model to evaluate the surgical treatment of patients entered into the intergroup trial of adjuvant 5-FU-based chemoradiation. The Kampschoer et al.²²⁵ program was used to estimate the likelihood of disease in undissected regional node stations, defining the sum of these estimates as the Maruyama index of unresected disease. Fifty-four percent of participating patients underwent D0 lymphadenectomy. The median index was 70 (range = 0 to 429). In contrast to D level, the Maruyama index proved to be an independent prognostic factor of survival, even with adjustment for the potentially linked variables of T stage and number of positive nodes. More recent and smaller studies confirmed these findings.^{229–231}

Preoperative Endoscopic Peritumoral Injection. The hypothesis that peritumoral injection of compounds designed to optimize lymph node dissection improves lymph node clearance was addressed in a small RCT evaluating preoperative endoscopic vital dye staining with CH40 prior to D2 dissection. The frequency of positive lymph nodes in patients injected with CH40 before D2 dissection was greater than that observed in patients treated by D2 dissection alone.²³² This approach optimized the yield of lymph node dissection presumably by directing surgeons to include specific lymph nodes in the dissection that might have otherwise been left in situ and/or by directing pathologists to examine specific areas of the lymphadenectomy specimens. Further prospective studies of this approach are required to confirm the feasibility of this technique and to assess its impact on intraoperative decision making regarding the extent of lymphadenectomy and accuracy of specimen dissection and nodal retrieval in anatomic pathology.

Sentinel Lymph Node Biopsy. The goal of SLN biopsy is to identify the node or nodes believed to be the first peritumoral lymph nodes in the orderly spread of gastric adenocarcinoma from the primary site to the regional lymph nodes. Sampling of this lymph node(s) may allow for prediction of the nodal status of the entire lymph node basin, possibly obviating extended nodal dissection and its attendant morbidity in patients found to have a negative SLN. Recent pilot studies have evaluated the feasibility, sensitivity, and specificity of SLN biopsy for patients with gastric cancer.^{233–242} These pilot studies demonstrated that SLN identification is feasible in approximately 95% of patients. However, most patients with gastric cancer have multiple “sentinel” nodes, with mean numbers of SLNs per patient ranging from 2.6 to 6.3. The aggregate experience to date suggests that among patients with pathologically involved lymph nodes, SLN results in false-negative assessment of pathologic regional nodal status in 11% to 60% of patients. Thus, the preliminary data available suggest that SLN biopsy cannot reliably replace lymph node dissection as a means of accurately staging regional nodal basins in gastric adenocarcinoma.^{243–247}

In a large study of nearly 400 patients, the ability and accuracy of SLNs was examined in a prospective, multicenter phase 2 study.²⁴⁸ Patients with early T stage gastric cancer (cT1 or cT2, tumor <4 cm) were evaluated with SLN mapping, followed by gastrectomy and D2 dissection. The SLN mapping technique identified 57 patients who had nodal involvement, of which 53 had true positive SLNs, resulting in 99% accuracy. Though further validation is needed, these results are quite encouraging.

The JCOG multicenter trial (JCOG-0302) assessed the feasibility and accuracy of indocyanine green (ICG) SLN mapping at time of surgery prior to gastrectomy and lymphadenectomy for EGC (T1).²⁴⁹ Single sections of ICG-stained SLNs were examined intraoperatively using frozen section with hematoxylin and eosin stain. The primary study end point was the proportion of false-negative SLNs. Study accrual was halted after 440 of the planned 1,550 patients were enrolled when the proportion of false negatives was found to be unexpectedly and unacceptably high (46%). The authors appropriately concluded that SLN mapping and biopsy using ICG and intraoperative single nodal frozen section evaluation using hematoxylin and eosin staining is inappropriate for clinical use in EGC.

Volume-Outcome Relationships for Gastrectomy. Recent studies have established a clear relationship between institutional gastrectomy volume and perioperative mortality rates—the so-called volume-outcome relationship. The recent analysis of a national database by Birkmeyer et al.^{250–252} of 31,854 patients who underwent gastrectomy between 1994 and 1999 demonstrated an inverse relationship between institutional gastrectomy volume and operative mortality rates. The odds ratio for gastrectomy-related death was lowest among patients treated within hospitals in the highest gastrectomy volume quintile (odds ratio = 0.72; 95% CI = 0.63 to 0.83). A separate analysis evaluating surrogate end points for morbidity demonstrated that gastrectomy at high-volume centers was associated with the shortest duration of hospital stay and the lowest readmission rates.^{253–256} Similar findings were noted by Hannan et al.²⁵⁷ in an analysis of the New York State Department of Health's administrative database. Their analysis of 3,711 patients who underwent gastrectomy between 1994 and 1997 included adjustments for covariates such as age, demographic variables, organ metastasis, socioeconomic status, and comorbidities. Patients who had a gastrectomy at hospitals in the highest-volume quartile had an absolute risk-adjusted mortality rate that was 7.1% ($p < 0.0001$) lower than those treated at hospitals in the lowest-volume quartile, although the overall mortality rate for gastrectomy was only 6.2%.

These studies demonstrate that the risk-adjusted mortality rates for gastrectomy are significantly lower when gastrectomy is performed by high-volume providers.^{258–261} It is likely that the variations in gastrectomy-related mortality rates relate in part to surgeon training and their patient age-volume^{262–264} and experience with the procedure. Data on gastrectomy volume obtained from general surgeons undergoing recertification after a minimum of 7 years in practice demonstrate that the mean number of gastric resections performed by recertifying general surgeons in the United States is only 1.4 per year.²⁶⁵ Thus, given the data supporting a relationship between hospital and provider volumes and the morbidity and mortality rate of gastric resection, there are reasons to consider regionalization of the surgical treatment of gastric cancers.

Outcome in Japan Versus Western Countries. Stage-stratified survival rates for gastric adenocarcinoma are higher in Japan than in most Western countries. The reasons for this are complex, are incompletely understood, and cannot be fully addressed within the context of a chapter covering all aspects of gastric cancers.

Important differences in the epidemiology of gastric cancer may contribute to observed differences in outcome in Japan versus Western countries. First, the better-prognosis intestinal-type (Laurén classification)²⁶⁶ tumors are seen more commonly in Japan, whereas the diffuse-type cancers (poorer prognosis) are

more frequent in Western series. These regional differences in the frequencies of intestinal and diffuse cancers are believed to be related to the higher incidence of *H. pylori* infection and atrophic gastritis in Japan. Second, poorer-prognosis proximal gastric cancers are less frequent in Japan.^{267–269} Indeed, the progressive increase in proximal gastric cancers observed in the West has not been observed in Japanese populations.

Regional differences in the diagnostic criteria for EGC also may contribute to regional differences in observed outcome. In Japan, gastric carcinoma is diagnosed based on its structural and cytologic features without consideration of invasion of the lamina propria. In contrast, Western pathologists consider invasion of the lamina propria to be an essential element of the diagnosis of carcinoma.^{270–274} As a consequence, unequivocally neoplastic noninvasive lesions are classified as carcinoma in Japan, but as dysplasia by Western pathologists.²⁷⁰ To overcome these differences, the Padova,²⁷⁵ Vienna,²⁷⁶ and Revised Vienna²⁷⁶ classifications have recently been proposed. However, until there is worldwide consensus and implementation of uniform diagnostic criteria for EGC, comparative assessments of the outcome of patients with EGC treated in Japan and Western countries should acknowledge the selection bias associated with different diagnostic criteria.

Stage migration is a well-documented factor contributing to the stage-specific differences in outcome between Japanese and Western patients.²⁷⁷ Stage migration arises because there is widespread use of extensive D2 or D3 lymphadenectomy combined with rigorous pathologic assessment of the lymphadenectomy specimen in Japan. More accurate stage assignment of Japanese patients leads to secondary stage migration—improvement in stage-specific survival without improvement in OS. The frequency and impact of stage migration were quantified by the Dutch Gastric Cancer Group in their RCT comparing D1 and D2 lymph node dissection.^{190,278} Stage migration occurred in 30% of patients in the D2 group, and the stage-specific decreases in survival rates attributable to stage migration were 3% for AJCC/UICC stage I disease, 8% for stage II, 6% for stage III, and 12% for stage IIIB, with the more accurately staged D2 group having higher survival rates.²⁷⁸

In addition to regional differences in epidemiology, diagnostic criteria for EGC, and stage migration, other factors may contribute to the observed differences in stage-stratified survival. Such factors may include genetic, environmental, and biologic differences between Japanese and Western patients and tumors. These factors have been less well studied, but were addressed in a comprehensive review by Davis and Sano.²⁷⁹

Outcome in Korea Versus Western Countries. A separate evaluation was performed comparing gastric cancer survival following curative intent resection in Korea versus the United States.¹²⁶ This study compared two independent, single-institution prospectively maintained databases from 1995 to 2005: one from MSKCC ($n = 711$ curatively resected patients who did not receive neoadjuvant therapy) and another from St. Mary's Hospital in Seoul, South Korea ($n = 1,646$ patients, also curatively resected without receiving preoperative therapy). All patients had a D2 dissection and adequate nodal staging. There were notable differences in the two cohorts: patients from the United States were more likely to have proximal tumors and more advanced stage compared with patients resected in Korea. However, when controlling for all known risk factors, stage for stage, patients from Korea still had better OS (HR = 1.3; 95% CI = 1.0 to 1.7; $p = 0.05$). These data cannot exclude differences in underlying cancer biology as a potential explanation for the observed differences in survival in gastric cancer between patients treated in Korea versus those treated in the United States.

Minimally Invasive Surgery for Gastric Resection

The utilization of laparoscopy in gastric surgery has been increasing over the past decade. There are a plethora of non-RCTs reporting on laparoscopic distal gastrectomy, total gastrectomy, and D2

dissection, and practically every open procedure has been tested using laparoscopy. We will review here the available data from published RCTs. There are no RCTs reporting on total gastrectomies.²⁸⁰ None of the current RCTs reporting on laparoscopy in gastric cancer are of sufficient quality and magnitude to be considered “practice changing.” Huscher et al.^{281,282} reported on the largest RCT testing laparoscopic ($n = 29$) versus open ($n = 30$) subtotal gastrectomy for distal gastric cancer. After 5 years of follow-up, overall morbidity and mortality were equivalent. Laparoscopic resection resulted in less blood loss, shorter hospital stay, longer operative time, and earlier resumption of oral intake; these were reported by other authors as well.^{283,284} There was no difference in the number of lymph nodes harvested. Overall 5-year and DFS did not differ significantly. The authors concluded that laparoscopic subtotal gastrectomy is feasible and has similar short- and long-term outcomes as open surgery.

Kim et al.²⁸⁵ reported on laparoscopy-assisted distal gastrectomy (LADG) versus open distal gastrectomy (ODG) for early gastric cancer. This trial was designed to test the 5-year survival utilizing noninferiority design. The interim analysis showed less blood loss ($p < 0.001$), reduced amount of analgesic used ($p < 0.019$), shorter hospital stay ($p < 0.0001$), fewer number of lymph nodes harvested in the LADG arm ($p < 0.05$), and improved short-term quality of life (QOL) parameters on global health ($p < 0.0001$). The authors concluded that comparison of LADG with ODG resulted in improved QOL outcomes in patients followed up to 3 months. The authors have now reported long-term follow-up data.²⁸⁶ In this study, the authors evaluated 2,976 patients who were treated with either laparoscopic gastrectomy (1,477 patients) or open gastrectomy (1,499 patients) between April 1998 and December 2005. With a median follow-up of 70.8 months, there was no difference in survival between the two resection methodologies, with the exception that for stage IA gastric cancer, laparoscopic gastrectomy had a improved survival (95.3% 5-year survival) versus open gastrectomy (90.3% 5-year survival) ($p < 0.001$).²⁸⁶ Recently, Ohtani et al.²⁸⁷ performed meta-analysis of RCT that compared LADG versus ODG for EGC. Their report confirmed the results from Kim et al.²⁸⁶ and Lee and Han.²⁸⁸

A recent update and meta-analysis analyzed data on 784 patients enrolled in eight RCTs²⁸⁹ comparing laparoscopy-assisted to open gastrectomy for resectable gastric cancer. Despite the fact that operative time was significantly prolonged in the laparoscopy group and that analgesic use, operative blood loss, nodal yield, morbidity (overall and anastomotic), and mortality were no different when compared with open gastrectomy, there were a number of clinically important benefits observed in those undergoing minimally invasive surgery. Pulmonary morbidity (odds ratio = 0.43; 95% CI = 0.20 to 0.93; $p = 0.03$), duration of postoperative ileus (missing data = -0.23; 95% CI = -0.41 to -0.05), and hospital stay (missing data = -1.72; 95% CI = -3.40 to 0.04) were significantly reduced in the laparoscopy-assisted gastrectomy group. The survival benefit of minimally invasive surgery in resectable gastric cancer has yet to be definitively demonstrated.²⁸⁹

Laparoscopy is another tool in the armamentarium of the surgical oncologist. The question is not whether it can be done laparoscopically, certainly it can; the question is whether it should be done in patients with gastric adenocarcinoma. Recently, a meta-analysis of six clinical trials (658 patients) compared laparoscopic versus open gastrectomy for distal EGC.²⁹⁰ In this analysis, the authors noted significant reductions in postoperative complications and length of hospital stay in the laparoscopic group, whereas the open gastrectomy group had less operating time and a greater number of lymph nodes harvested. There were no notable differences in the time to return of bowel function, incidence of wound infection, postoperative abscess formation, or anastomotic leak or pulmonary complications, suggesting that there may be some advantages of the laparoscopic approach. The oncologic equivalence, however, has not been adequately tested. Whether the energy, time, and capital invested in developing laparoscopic surgery for gastric

cancer is worth it is the relevant question particularly in an era of skyrocketing medical costs. Certainly, beyond the short term there seems to be no advantage of laparoscopic surgery in gastric cancer. In view of the reported morbidity and mortality in specialty centers, the advantage gained by laparoscopic gastric resection over the first few days underlines the question of whether we should invest more in innovative therapies to eradicate gastric cancer than the simple technical aspects of noninvasive extirpative surgery.

A large prospective random assignment study from Korea is underway in which 1,415 patients with EGC (pT1-2 N0) are randomly assigned to receive either open or laparoscopic distal gastrectomy.²⁹¹ Final results of this expected “definitive” phase 3 study are expected to be available in September 2015. A similar large phase 3 study for stage IA and stage IB gastric cancer was initiated in Japan in March 2010. This study randomizes 920 patients from 33 institutions, with the primary end point of OS.²⁹² Together, it is anticipated that these two pivotal studies will definitively define the role of laparoscopic-assisted gastrectomy in EGC.

Adjuvant Therapy

Patients with EGCs (e.g., patients with AJCC stage I and some stage II) have a good chance of cure with surgery alone. However, the Japanese S-1 adjuvant study indicates that the prognosis for even stage II tumors can be improved with systemic chemotherapy.

Adjuvant therapy indicates administration of a treatment following a potential curative resection of the primary tumor and regional lymph nodes. Therapy after resections that leave microscopic or gross disease are not adjuvant treatment, but rather therapy for known disease, which is palliative in nature. Neoadjuvant chemotherapy involves the use of systemic treatment before potentially curative surgery.

There are several theoretical reasons for beginning adjuvant therapy soon after operation (perioperative chemotherapy). Studies have shown a rapid increase in cell growth of metastases after a primary tumor has been removed related to a decline in certain circulating factors, which serve to inhibit angiogenesis or other cell-cycle promoters, once the primary tumor is removed. Perioperative or neoadjuvant chemotherapy has been studied because the ability to perform a R0 resection in gastric cancer is difficult. In addition, a substantial number of patients undergoing gastrectomy have prolonged recovery. Neoadjuvant chemotherapy has a dual goal: allowing a higher rate of R0 resections and treatment of micrometastatic disease early in the course of treatment.

Adjuvant Systemic Therapy. The results of selected recent RCTs comparing adjuvant chemotherapy with surgery alone are summarized in Table 46.5. Japanese investigators studied S-1, an oral fluoropyrimidine, in a group of 1,059 patients (stages II to IIIB). S-1 was given for 12 months (4 weeks on/2 weeks off). A total of 529 patients received S-1 plus operation and 530 patients underwent operation only. The 3-year OS was 80.1% and 70.1%, respectively (HR = 0.68).²⁹³

The 5-year survival update was recently reported and demonstrated a sustained benefit in 5-year OS of 71.7% with adjuvant S-1 versus 61.1% with surgery alone (HR = 0.669; 95% CI = 0.540 to 0.828).²⁹⁴ In addition, another Asian study from Korea reported the results of adjuvant capecitabine and oxaliplatin.²⁹⁵ In this study, patients were required to have a D2 resection, and those with stage II-IIIIB were then randomly assigned to receive 6 months (eight cycles) of capecitabine/oxaliplatin or observation. This was a large study, in which 520 patients were randomly assigned to receive adjuvant chemotherapy and 515 to surgery alone. The study met its primary endpoint of 3-year DFS (74% [95% CI = 69 to 79] with chemotherapy versus 59% [53% to 64%] with surgery alone; $p < 0.0001$). In contradistinction to the positive results using S-1, and the MAGIC and ACCORD 07 trials described later, Di Costanzo et al.²⁹⁶ did not find a benefit to the use of cisplatin, epirubicin, leucovorin, and 5-FU as adjuvant therapy.

^a Five-year DFS.

Several meta-analyses of adjuvant chemotherapy in gastric cancer have been reported. Recently, Buyse et al.²⁹⁷ reported a meta-analysis that included individual patient data; 16 trials involving 3,710 patients were available for analysis. They found an OS benefit in favor of adjuvant chemotherapy (HR = 0.83; 95% CI = 0.76 to 0.91; $p < 0.0001$). The absolute benefit was 6.3% at 5 years. The GASTRIC group conducted a meta-analysis; as of 2010, individual patient data for 17 trials involving 3,838 patients were available for analysis. They found an OS benefit in favor of adjuvant chemotherapy (HR = 0.82; 95% CI = 0.75 to 0.90; $p > 0.001$). The absolute benefit was 5.9% at 5 years.²⁹⁸ Shown in Table 46.5 are the results of recent trials in which adjuvant chemotherapy plus potentially curative resection was studied. The five most recent trials indicate that adjuvant therapy decreases the risk of recurrence by approximately 10%.²⁹⁹ The use of systemic therapy plus potentially curative resection is considered a standard of care for patients with locally advanced gastric cancers. The most effective regimen to use, whether or not it is best to give therapy perioperatively, and the role of postoperative radiation plus systemic therapy are the focus of ongoing clinical research trials.

Adjuvant Intraperitoneal Chemotherapy. Peritoneal recurrence is a common pattern of failure for patients with gastric cancer, even after curative resection.^{31,298} The median survival time of patients with peritoneal recurrence is 3 to 6 months. The rationale is based on the observation that drug concentrations within the peritoneal cavity are much higher than those achievable by intravenous or oral drug administration. The data are a mixture of retrospective reviews, pilot phase 2 trials, and several small phase 3 trials. No definitive conclusions can yet be drawn regarding the effectiveness of intraperitoneal postoperative chemotherapy in this setting.

There are several modes of administering intraperitoneal chemotherapy: hyperthermic intraoperative peritoneal chemotherapy (HIPEC), normothermic intraoperative chemotherapy (NIIC) given at the conclusion of the operation, early postoperative

intraperitoneal (normothermic) chemotherapy (EPIC), or delayed postoperative intraperitoneal (normothermic) chemotherapy. The theoretical advantage of intraoperative treatment is better drug distribution and the ability to use hyperthermia (HIPEC) to enhance microscopic tumor cytotoxicity. Most trials in gastric cancer have used either 5-FU or floxuridine, mitomycin C, or cisplatin for intraperitoneal chemotherapy.³⁰⁰⁻³⁰⁹ Yan et al.³¹⁰ performed a meta-analysis of the RCTs reporting on adjuvant intraperitoneal chemotherapy for patients undergoing curative gastric resection; 10 trials involving 1,474 patients were included. A total of 775 patients had resection alone, and 873 patients had resection plus intraperitoneal treatment. A significant improvement in survival was associated with HIPEC (HR = 0.6; 95% CI = 0.43 to 0.83; $p = 0.002$) or HIPEC plus EPIC (HR = 0.45; 95% CI = 0.29 to 0.68; $p = 0.0002$). There was only a trend toward survival benefit with NIIC ($p = 0.06$), but this was not significant with either EPIC alone or delayed postoperative intraperitoneal (normothermic) chemotherapy. The authors concluded that HIPEC with or without EPIC after curative gastric resection is associated with modest improvement in survival and increased complication rate.

Recently, Kang et al.³¹¹ reported on 640 patients with serosal-positive gastric cancer who underwent resection and were then randomized to receive intravenous mitomycin-C (20 mg/m²) at 3 to 6 weeks after surgery and oral doxifluridine (460 to 600 mg/m² per day) starting 4 weeks after the administration of mitomycin-C and continuing for 3 months, or to receive intraoperative intraperitoneal cisplatin (100 mg), intravenous mitomycin-C (15 mg/m²) on postoperative day 1, followed by oral doxifluridine for 12 months, and six monthly intravenous cisplatin (60 mg/m²). Results indicated potential improvement in progression-free survival (PFS) and OS for the intraperitoneal cisplatin therapy arm. Kuramoto et al.³¹² reported in a retrospective fashion that extensive intraperitoneal lavage performed with 10 L of normal saline after curative resection and before NIIC is superior to surgery alone or to surgery plus NIIC.

Immunochemotherapy

The use of adjuvant immunostimulants given in combination with cytotoxic chemotherapy (immunochemotherapy) has been studied primarily in Asia. The detailed results of these trials have been discussed in the previous edition of this textbook. Although the data available suggest that immunochemotherapy may be valuable, larger and adequately powered clinical trials are necessary to evaluate the clinical utility and efficacy this approach.

Perioperative and Neoadjuvant Chemotherapy. Perioperative (pre- and postoperative) or neoadjuvant chemotherapy is an attractive concept in gastric cancer because many patients have locally advanced tumors at diagnosis, particularly in Western countries. There are two goals of perioperative treatment: to increase the likelihood of an R0 resection, and treat micrometastatic disease early. After gastric resection, many patients have a prolonged recovery, delaying initiation of adjuvant therapy. Phase 2 trials involving either purely preoperative or perioperative treatment demonstrated that there was no increase in anticipated surgical morbidity or mortality when compared to controls.^{313,314} Brenner et al.³¹⁴ reported on patients with locally advanced, high-risk gastric cancer who received preoperative CF followed by intraperitoneal chemotherapy after resection. At 43 months of follow-up, 39.5% of patients were still alive. Evaluating efficacy at the primary site is difficult in gastric cancer. Kelsen et al.³¹⁵ compared EUS with pathologic stage in assessing objective regression after neoadjuvant chemotherapy. They found that even though EUS was an accurate test in previously untreated patients following administration of chemotherapy, after chemotherapy and prior to surgery, EUS was inaccurate in measuring the depth of invasion (T stage) or lymph node involvement.

FDG-PET scan as a predictive marker of response to preoperative chemotherapy has been studied in patients with gastric cancer. Ott et al.⁷⁷ reported on 44 patients with locally advanced gastric cancer who underwent PET scans prior to and after receiving chemotherapy. A decreased SUV was able to differentiate between patients who responded pathologically to treatment and those who did not.³¹⁵ These data suggest that functional imaging may eventually prove to be a useful predictive marker for efficacy. Studies in which systemic therapy is changed on the basis of an early PET scan are now under way. As previously noted, for patients with gastric cancer, approximately 20% to 25% of patients will not have an informative PET scan, so this technique cannot be used as a predictive marker for these patients.

FDG-PET and PET/CT scan are being evaluated in Japan as a potentially useful modality for the purpose of gastric cancer. A recently published trial from the National Center for Global Health and Medicine in Tokyo studied over 150,000 asymptomatic patients as part of it FDG-PET screening.³¹⁶ With a sensitivity and positive predictive value of 38% and 34%, respectively, the authors appropriately concluded that gastric endoscopy should be included as part of screening programs in order to increase rate of gastric cancer detection.³¹⁶

After phase 2 studies demonstrated safety and suggested efficacy, several perioperative chemotherapy phase 3 trials were conducted (see Table 46.5). English investigators led by Cunningham et al.³¹⁷ reported the final results of a well-designed, random assignment study comparing surgery alone with surgery and perioperative chemotherapy in patients with gastroesophageal junction and gastric cancers (the MAGIC trial). All patients had potentially resectable disease prior to entrance into the study. Patients assigned to perioperative chemotherapy were treated with the epirubicin-cisplatin-5-FU (ECF) regimen. Chemotherapy was given both before and after surgery. A total of 503 patients were entered into the study; three-quarters had gastric cancer and one-quarter had gastroesophageal junction or lower esophageal adenocarcinomas. The ECF chemotherapy was well tolerated, with no increase in surgical morbidity or mortality. There was a shift to an earlier stage overall in patients receiving perioperative chemotherapy, as well as an improved R0 resection rate. With a median follow-up of 4 years, there was a significant improvement in both disease-free and OS for patients receiving perioperative chemotherapy: 5-year survival rate was 36% for those receiving perioperative chemotherapy and 23% for those receiving surgery alone (HR = 0.75; 95% CI = 0.6 to 0.9; $p = 0.009$). The authors concluded that ECF perioperative chemotherapy improves outcome for patients with resectable gastric cancer without increasing operative morbidity or mortality. This important trial was a well-designed, adequately powered study demonstrating an advantage of systemic treatment plus surgery when compared with operation alone.

More recently, French investigators reported the results of a similar trial (ACCORD 07-FFCD 9703) using CF prior to surgery versus surgery alone.³¹⁸ Approximately half the patients receiving preoperative chemotherapy also received postoperative treatment using the same regimen. The results were similar to those of the MAGIC trial, with 5-year OS being 24% for those undergoing operation alone versus 30% for those who received perioperative chemotherapy. There was a similar improvement in DFS. The results of the ACCORD 07 trial support the results of the MAGIC study.

Summary for Neoadjuvant Chemotherapy. The results of the MAGIC and ACCORD 07 trials have shown that systemic chemotherapy regimens that are only modestly effective in palliating patients with advanced disease can have a small but clinically meaningful effect on survival when given in the perioperative setting. New and potentially effective cytotoxic agents as well as new biologic agents are now being introduced in the treatment of patients with gastric malignancy. Studies involving perioperative chemotherapy using these agents are now in the advanced planning stage. The results of the perioperative chemotherapy, MAGIC and

ACCORD 07, trials and of postoperative S-1, and Intergroup Trial (INT 0116) chemoradiation studies support the use of systemic therapy as an important component of the treatment plan for patients with locally advanced gastric cancers. The best strategy to pursue—that is, whether to give systemic therapy first followed by operation or to proceed directly to operation followed by systemic treatment plus or minus radiation given after surgery—has yet to be determined.

Given that the role of neoadjuvant chemotherapy in gastric cancer remains controversial, a systematic review and meta-analysis of six RCTs (aggregate $n = 781$) was conducted to gain insights about the potential benefit of neoadjuvant chemotherapy followed by surgery as compared to surgery alone.³¹⁹ Outcomes analyzed in this meta-analysis were OS, rate of R0 resection, downstaging effect of neoadjuvant chemotherapy, operative morbidity, and mortality. No significant difference were evident when comparing neoadjuvant chemotherapy and surgery to surgery alone for these outcome variables; odds ratios were as follows for OS 1.16 (0.85 to 1.58; $p = 0.36$), R0 resection 1.24 (0.78 to 1.96; $p = 0.36$), operative morbidity 1.25 (0.75 to 2.09; $p = 0.39$), and mortality 3.60 (0.59 to 22.45; $p = 0.17$).

Adjuvant Radiation and Chemoradiation Therapy. The recognition of the high rates of local and regional failure following surgery in patterns of failure analyses has served as the basis for clinical trials assessing the value of radiation therapy with and without chemotherapy as an adjuvant treatment in gastric cancer. Although these studies have all addressed the important question of whether clinical outcome is enhanced by adjuvant radiation therapy, there has been marked variability in radiation dose and schedule, sequence with surgery (preoperatively, intraoperatively, or postoperatively), and the use of concurrent and maintenance chemotherapy. These differences in study design may explain in part the conflicting results observed in phase 3 studies.

Two randomized phase 3 trials have studied the use of external beam radiation therapy (EBRT) alone with surgery.^{320–322} Although both studies used similar radiation dose and schedule, sequence with surgery differed. In the British Stomach Cancer Group study, 436 patients were randomized to surgery alone, postoperative radiation therapy (45 to 50 Gy in 25 to 28 fractions), or cytotoxic chemotherapy with mitomycin, doxorubicin, and 5-FU.^{320,321} The 5-year survival for surgery alone was 20%, for surgery plus radiation therapy 12%, and for surgery plus chemotherapy 19%. In this study, no survival advantage was observed for patients who received postoperative EBRT, although there was an apparent improvement in local control, demonstrating that local disease could be affected by adjuvant radiation therapy. Locoregional failure was documented in only 15 of 153 (10%) in the radiation arm versus 39 of 145 (27%) in the surgery-alone arm, and 26 of 138 (19%) in the mitomycin, doxorubicin, and 5-FU group. Interpretation of these results is complicated by the inclusion of 171 patients undergoing resection with gross or microscopic residual carcinoma. These patients would not be candidates for current gastric surgical adjuvant trials in the United States. In addition, approximately one-third of patients randomized to receive adjuvant treatment did not receive the assigned therapy. Of 153 patients randomized to the postoperative radiation arm, only 104 (68%) received a dose of 40.5 Gy or more, and 36 (24%) received none.

In contrast, the results of a phase 3 study from Beijing demonstrated a survival benefit for patients with gastric cardia carcinoma receiving preoperative radiation and surgery versus surgery alone.³²² In this study, 370 patients with gastric cardia carcinoma were randomized to 40 Gy in 20 fractions over 4 weeks of preoperative irradiation and surgery or surgery alone. The 5-year survival rates of preoperative radiation and surgery and the surgery-alone group were 30% and 20%, respectively (10-year, 20% and 13%, respectively; $p = 0.009$). Further, both local and regional nodal control was improved in patients undergoing preoperative radiation and surgery (61% and 61%, respectively) versus surgery

(48% and 45%, respectively) only. Morbidity and mortality rates were not increased in patients receiving preoperative therapy.³²³

As the price role of adjuvant radiation in resectable gastric cancer remains controversial, an updated systematic review and meta-analysis of 13 RCTs³²⁴ was conducted to gain insights about the potential benefit of adjuvant (including neoadjuvant) radiation and surgery versus surgery alone for resectable gastric cancer.³²³ Outcomes analyzed in this meta-analysis were OS, and DFS. Postoperative radiation was associated with a significant improvement in both OS (HR = 0.78; 95% CI = 0.70 to 0.86; $p < 0.001$) and DFS (HR = 0.71; 95% CI = 0.63 to 0.80; $p < 0.001$). Similar improvement in OS (HR = 0.83; 95% CI = 0.67 to 1.03; $p = 0.087$) and DFS (HR = 0.77; 95% CI = 0.91 to 0.65; $p = 0.002$) was observed in five RCTs comparing surgery + adjuvant chemoradiation to surgery + adjuvant chemotherapy for resectable gastric cancer. This meta-analysis suggests that radiation following gastrectomy translates to ~20% DFS and OS benefit.

An alternative approach to postoperative or preoperative radiation is intraoperative radiation therapy (IORT).³²⁵ The advantage of this technique is the ability to deliver a single large fraction (10 to 35 Gy) of radiation to the tumor or tumor bed while excluding or protecting surrounding normal tissue from the high-dose field. This approach permits high-dose radiation with minimal normal tissue treatment. Two randomized trials have examined the efficacy of IORT in combination with surgery for patients with gastric carcinoma.^{326,327} Abe et al.³²⁶ from Kyoto University performed a randomized trial of 211 patients with gastric cancer comparing surgery alone with surgery and IORT (28 to 35 Gy). For patients with tumor confined to the gastric wall (stage I), 5-year survival rates were similar for IORT and for resection alone. However, patients with Japanese stages II to IV disease who received IORT in conjunction with resection showed improved survival over patients who underwent resection without radiation. Among patients with stage IV disease (who usually had local residual disease after maximal resection), there were no 5-year survivors who received surgery alone; however, 15% of the patients who received IORT were alive at 5 years. The experience with IORT in gastric cancer at Kyoto University suggested that IORT may be beneficial in the treatment of locally advanced carcinoma of the stomach.

To further evaluate this approach, Sindelar et al.³²⁷ at the National Cancer Institute conducted a prospective RCT comparing surgical resection and IORT with conventional therapy in gastric carcinoma. Patients in the experimental group underwent gastrectomy, and IORT was administered to the gastric bed (20 Gy). Patients in the control group underwent resection and postoperative EBRT to the upper abdomen (50 Gy in 25 fractions) for advanced-stage cancers extending beyond the gastric wall. Of the 100 patients screened for the study, 60 were randomized and underwent exploratory surgery. Nineteen patients were excluded intraoperatively because of unresectability or metastases, leaving 41 patients in the study. The median survival for patients with tumors of all stages was 25 months for the IORT group and 21 months for the control group ($p = \text{NS}$). Locoregional disease relapse occurred in 7 of 16 IORT patients (44%), and in 23 of 25 patients (92%) control patients ($p < 0.001$). Complication rates were similar between IORT and control patients. Although IORT was not associated with a significant advantage over conventional therapy in terms of OS, IORT did significantly improve locoregional disease control. Based on these results, the use of IORT in gastric cancer remains investigational.

Because of the promising results in the early studies of combined-modality therapy for locally advanced (unresectable) or subtotally resected gastric cancer, investigators also have studied this combination of surgery and radiation in resectable gastric carcinoma. A small study from South Africa randomized 66 patients with resected gastric cancer (T (1–3), N (1–2), M0) to low-dose postoperative radiation (20 Gy in eight fractions over 10 days) and 5-FU, or to no further therapy after surgery.³²⁸ No difference in survival was observed between the patients undergoing surgery and adjuvant

therapy and those undergoing surgery alone. Given the subtherapeutic doses of radiation used in this study, it is difficult to draw any definitive conclusions as to the efficacy of adjuvant radiation therapy and 5-FU. In 1984, Moertel et al.³²⁹ reported the results of a prospective randomized trial conducted at the Mayo Clinic with 62 patients with poor prognosis, but completely resected gastric cancers who were randomized to either surgery alone or surgery followed by radiation (37.5 Gy in 24 fractions over 4 to 5 weeks) with concurrent 5-FU. A nonstratified, prerandomization scheme was used with a 2:3 ratio favoring treatment. Ten of the thirty-nine patients refused further therapy and were observed. When analyzed by intent to treat, the adjuvant arm had statistically significant improvement in both relapse-free survival and OS (overall 5-year survival 23% versus 4%; $p < 0.05$). When patient outcome was compared with actual treatment received (29 adjuvant treatment, 33 surgery alone), 5-year survival continued to favor the adjuvant group (20% versus 12%), but the differences were not statistically significant in view of the small patient numbers. The 10 patients who refused assignment to adjuvant treatment had more favorable prognostic findings than the other two groups of patients. When the two groups with equally poor prognostic factors were compared, the 5-year OS was 20% versus 4%, with an advantage to those receiving adjuvant radiation and 5-FU treatment. When analyzed by treatment delivered, locoregional relapse was decreased with adjuvant treatments (54% with surgery alone versus 39% with irradiation and 5-FU).

The Intergroup Trial (INT 0116) randomized patients to receive surgery alone or surgery plus postoperative 5-FU-based chemotherapy and radiation.³³⁰ The trial included patients with stages IB–IVA nonmetastatic adenocarcinoma of the stomach or GEJ. After en bloc resection, 556 patients were randomized to either observation alone or postoperative combined-modality therapy consisting of one monthly 5-day cycle of 5-FU and leucovorin, followed by 45 Gy in 25 fractions plus concurrent 5-FU and leucovorin (4 days in week 1, 3 days in week 5) followed by two monthly 5-day cycles of 5-FU and leucovorin. Nodal metastases were present in 85% of the cases. With 5 years of median follow-up, 3-year relapse-free survival was 48% for adjuvant treatment and 31% for observation ($p = 0.001$); 3-year OS was 50% for treatment and 41% for observation ($p = 0.005$). The median OS in the surgery-only group was 27 months, compared with 36 months in the chemoradiotherapy group; the HR for death was 1.35 (95% CI = 1.09 to 1.66; $p = 0.005$). The hazard ratio for relapse in the surgery-only group as compared with the chemoradiotherapy group was 1.52 (95% CI = 1.23 to 1.86; $p < 0.001$). The median duration of relapse-free survival was 30 months in the chemoradiotherapy group and 19 months in the surgery-only group. Patterns of failure were based on the site of first relapse only and were categorized as local, regional, or distant. Local recurrence occurred in 29% of the patients who relapsed in the surgery-only group and 19% of those who relapsed in the chemoradiotherapy group. Regional relapse, typically abdominal carcinomatosis, was reported in 72% of those who relapsed in the surgery-only group and 65% of those who relapsed in the chemoradiotherapy group. Extra-abdominal distant metastases were diagnosed in 18% of those who relapsed in the surgery-only group and 33% of those who relapsed in the chemoradiotherapy group. Treatment was tolerable, with three (1%) toxic deaths. Grade 3 and 4 toxicity occurred in 41% and 32% of cases, respectively. The results of this large study demonstrate a clear survival advantage for the use of postoperative chemoradiation and strongly support the integration of postoperative chemoradiation into the routine care of patients with curatively resected high-risk carcinoma of the stomach and GEJ.

The US Gastrointestinal Intergroup has recently completed a second randomized prospective trial (Cancer and Leukemia Group B 80101) in patients with completely resected high-risk gastric cancer, comparing two chemotherapy regimens given before and after 5-FU-based chemoradiation. This study examines the use of one cycle of postoperative ECF (epirubicin 50 mg/m², cisplatin 60 mg/m², and continuous infusion 5-FU 200 mg/m² per day for 21 days) followed by radiation therapy with concurrent

continuous infusion 5-FU (200 mg/m² per day) and two additional cycles of ECF. This is compared with one cycle of postoperative 5-FU and leucovorin followed by concurrent continuous infusion 5-FU (200 mg/m² per day) and two additional cycles of 5-FU and leucovorin. This study was recently reported in abstract form and failed to demonstrate a survival advantage of the addition of ECF therapy to standard 5-FU and leucovorin.³³¹

To address the important question of the value of postoperative radiation following D2 resection, a Korean phase 3 study comparing postoperative cisplatin/capecitabine (XP) versus postoperative XP with capecitabine and radiation was reported.³³² In this study, 458 patients were enrolled, with 228 randomly assigned to receive adjuvant chemotherapy (XP for six cycles) and 230 patients assigned to receive adjuvant chemoradiation (XPx2 → capecitabine and radiation → XPx2). Although the primary end point of improved 3-year DFS was not met ($p = 0.862$), in the subset of patients with node-positive gastric cancer ($n = 396$), adjuvant chemoradiotherapy was associated with a superior DFS (HR = 0.6865; 95% CI = 0.4735 to 0.9952; $p = 0.471$). Based on these intriguing data, the investigators have initiated a confirmatory study limited to patients with lymph node–positive resected gastric cancer (ARTIST-II).

To address the role of adjuvant chemoradiation in light of the MAGIC trial, the Dutch Colorectal Cancer Group has initiated the CRITICS trial. This study is a phase 3 prospective randomized trial that investigates whether chemoradiotherapy (45 Gy in 5 weeks with daily cisplatin and capecitabine) after preoperative chemotherapy (3 × epirubicin, cisplatin, and capecitabine) and adequate (D1+) gastrectomy leads to improved survival in comparison with postoperative chemotherapy alone (3 × epirubicin, cisplatin, and capecitabine). Further evaluating the role of adjuvant radiation therapy, a Korean phase 3 trial (the ARTIST study) is randomizing patients undergoing D2 gastrectomy to adjuvant cisplatin and capecitabine, with or without radiation therapy.

Although no phase 3 trials have tested the value of preoperative radiation plus chemotherapy for patients with gastric cancer, two phase 2 trials for patients with esophagus cancer have included either lesions of the gastric cardia or the EGJ.^{333,334} In both trials, the trimodality study arm demonstrated an improvement in OS when compared with the control arm of surgery alone. The series by Walsh et al.³³³ (adenocarcinoma of the esophagus or gastric cardia) demonstrated a median survival of 16 months versus 11 months, and 3-year survival of 32% versus 6% ($p = 0.01$), with the statistically significant advantage to trimodality treatment. The US GI Intergroup phase 3 trial (adenocarcinoma or squamous cell of esophagus or EGJ), which closed prematurely because of low accrual, reported a median survival of 54 months versus 22 months, and 5-year survival of 39% versus 16% ($p = 0.008$), with a significant advantage associated with the trimodality arm.³³⁴ In addition, a recent phase 3 randomized German trial compared preoperative chemotherapy alone (5-FU, leucovorin, and cisplatin) versus the same regimen followed by low-dose radiation therapy (30 Gy) with concurrent cisplatin and etoposide in patients with adenocarcinoma of the lower esophagus or gastric cardia. Although the trial was closed early because of poor accrual (126 patients), patients receiving radiation therapy had significantly higher pathologic complete response rates (2% versus 16%; $p = 0.03$) and trend toward improved survival (3-year survival 47% versus 28%; $p = 0.07$).³³⁵

Preoperative chemoradiation data for patients with gastric cancer exclusively is limited to phase 2 studies from single institutions and cooperative groups. The MD Anderson Cancer Center has reported a study in which 33 patients completed a preoperative protocol that started with induction chemotherapy of 5-FU, leucovorin, and cisplatin, followed by 45 Gy of radiation therapy in 25 fractions over 5 weeks with concurrent infusional 5-FU. In 28 patients (85%), a gastrectomy was performed and D2 lymph node dissection was attempted. Pathologic complete and partial responses were found in 64% of all operated patients. These patients showed a significant longer median survival of 64 months in

comparison with 13 months in patients with tumors that showed no pathologic response to preoperative chemoradiation.³³⁶ In a study from the same institution, 41 patients with operable gastric cancer received two cycles of continuous 5-FU, paclitaxel, and cisplatin followed by 45 Gy of radiation therapy with concurrent 5-FU and paclitaxel. An R0 resection was achieved in 78% of patients; pathologic complete response was seen in 25% and pathologic partial response in 15% of patients. Pathologic response, R0 resection, and postoperative T and N stage correlated with overall and DFS.³³⁷

The Radiation Therapy Oncology Group (RTOG 9904) reported the results of a phase 2 study of 49 patients undergoing induction 5-FU, leucovorin, and cisplatin followed by concurrent radiation therapy, and infusional 5-FU and paclitaxel. Resection was attempted 5 to 6 weeks after chemoradiation. The pathologic complete response and R0 resection rates were 26% and 77%, respectively. At 1 year, more patients with tumors exhibiting a pathologic complete response (89%) were alive than patients with tumors having less favorable pathologic treatment response (66%). Grade 4 toxicity occurred in 21% of patients. These data appear to support a phase 3 study evaluating preoperative radiation therapy and chemotherapy versus postoperative radiation therapy and chemotherapy.³³⁸

TECHNICAL TREATMENT-RELATED ISSUES

Surgery

Surgery begins with careful laparoscopic staging and examination. Inspection for the presence of ascites, hepatic metastases, peritoneal seeding, disease in the pelvis (such as a “drop” metastasis), or ovarian involvement should be performed. Once distant metastases have been ruled out, depending on the location of the lesion, a bilateral subcostal incision or a midline abdominal incision can be used to gain adequate exposure to the upper abdomen. The stomach should be inspected to assess the location and extent of the primary tumor. The size and location of the primary tumor dictate the extent of gastric resection. A D2 lymphadenectomy sparing the spleen and pancreas can be done safely, and provides an excellent surgical specimen for pathologic staging, but this procedure should only be performed by or with an experienced surgeon.

The D2 subtotal gastrectomy commences with mobilization of the greater omentum from the transverse colon. After the omentum is mobilized, the anterior peritoneal leaf of the transverse mesocolon is incised along the lower border of the colon, and a plane is developed down to the head of the pancreas. The infrapyloric lymph nodes are dissected and the origin of the right gastroepiploic artery and vein are ligated. With a combination of blunt and sharp dissection, the plane of dissection continues on to the anterior surface of the pancreas, extending to the level of the common hepatic and splenic arteries. This maneuver can be tedious, but it theoretically provides additional protection against serosal spread of tumor to the local peritoneal surface. The right gastric artery is ligated. At this point, the duodenum is divided distal to the pylorus. The stomach and omentum are then reflected cephalad. The gastrohepatic ligament is divided close to the liver up to the gastroesophageal junction. Dissection is then continued along the hepatic artery toward the celiac axis. Once near the celiac axis, the lymph node–bearing tissue is dissected until the left gastric artery is visualized and can be divided at its celiac origin. The proximal peritoneal attachments of the stomach and distal esophagus can then be incised, and the proximal extent of resection is defined. For tumors of the mid- and proximal stomach, dissection of the lymph nodes along the splenic artery and splenic hilum is important. This technique is not indicated for antral tumors, given the low rate of splenic hilar nodal metastases seen with tumors in this anatomical location. The stomach is then divided 5 cm

proximal to the tumor, which dictates the extent of gastric resection. Despite the fact that the entire blood supply of the stomach has been interrupted, a cuff of proximal stomach invariably shows good vascularization from the feeding distal esophageal arcade. When feasible, most surgeons prefer to anastomose jejunum to stomach rather than to esophagus because of the technical ease and excellent healing seen with gastrojejunal anastomosis. Reconstruction using a variety of techniques has been described and is a matter of personal choice.

Antibiotics Prophylaxis

One RCT ($n = 501$) tested single-dose cefazolin or ampicillin-sulbactam 30 minutes before surgery versus multiple dose regimen for 3 days postoperatively. There were no differences in surgical site infections or complication.^{280,339}

Nasogastric Drainage After Gastrectomy

The Italian Total Gastrectomy Study Group reported on the largest RCT comparing total gastrectomy with Roux-en-Y with and without nasogastric tube ($n = 237$). There were no differences in overall morbidity, leak rate, hospital stay, and time to diet.³⁴⁰ Other authors confirmed that nasogastric tube is not necessary after gastrectomy.³⁴¹⁻³⁴³

Intraperitoneal Drains After Gastrectomy

As with other pathologies, two RCTs concluded that drains after gastrectomy are generally not indicated, and in certain situations can increase significantly operative morbidity.^{344,345}

Reconstruction After Gastrectomy

Iivonen et al.³⁴⁶ compared Roux-en-Y with and without pouch. They randomized 48 patients and found significantly less dumping syndrome and early satiety but with no differences at 15 months of follow-up. Fein et al.³⁴⁷ reported on 138 patients randomized in a similar fashion; they found similar QOL at 1 year but significantly improved QOL at 3-, 4-, and 5-year follow-up. It seems that reconstruction with pouch has long-term advantages and may be recommended as the standard reconstruction.²⁸⁰

Radiation Treatment

Technique of Radiation Therapy

Idealized portals generated from patterns of failure data should be modified on the basis of the individual patient's initial extent of disease.^{348,349} Based on the likely sites of locoregional failure, the gastric/tumor bed, anastomosis and gastric remnant, and regional lymphatics should be included in most patients undergoing post-gastrectomy radiation.³⁵⁰⁻³⁵³ Major nodal chains at risk include the lesser and greater curvature; celiac axis; pancreaticoduodenal, splenic, supra-pancreatic, and porta hepatis groups; and, in some, para-aortic to the level of mid-L3.

The relative risk of nodal metastases at a specific nodal location depends on both the site of origin of the primary tumor, and other factors including width and depth of invasion of the gastric wall.³⁴⁹ Tumors that originate in the proximal portion of the stomach and the GEJ have a higher propensity of spread to nodes in the mediastinum and pericardial region, but a lower likelihood of involvement of nodes in the region of the gastric antrum, periduodenal area, and porta hepatis. Tumors that originate in the body of the stomach can spread to all nodal sites, but have the highest likelihood of spreading to nodes along the greater and lesser curvature near the location of the primary tumor mass. Tumors that originate in the distal stomach, in the region of the gastric antrum, have a high likelihood of spread to the periduodenal, peripancreatic, and porta hepatis nodes, whereas they have a lower likelihood of spread

to the nodes near the cardia of the stomach, the periesophageal and mediastinal nodes, or to the splenic hilar nodes. Any tumor originating in the stomach has a high propensity of spread to nodes along the greater and lesser curvature, although they are most likely to spread to those sites in close anatomic proximity to the primary tumor mass. Guidelines for defining the clinical target volume for postoperative irradiation fields have been developed based on location and extent of the primary tumor (T stage), and location and extent of known nodal involvement (N stage).³⁴⁹ In general, for patients with node-positive disease, there should be wide coverage of tumor bed, remaining stomach, resection margins, and nodal drainage regions. For node-negative disease, if there is a good surgical resection with pathologic evaluation of at least 15 nodes, and there are wide surgical margins proximal and distal to the primary tumor (at least 5 cm), treatment of the nodal beds is optional. Treatment of the remaining stomach should depend on a balance of the likely normal tissue morbidity and the perceived risk of local relapse in the residual stomach.

Although parallel-opposed anteroposterior/posteroanterior (AP/PA) fields are a practical arrangement for tumor bed and nodal irradiation, three-dimensional multifield techniques should be used if they can improve long-term tolerance of normal tissues. Tightly contoured fields should be designed to spare as much normal tissue as possible. Over the past decade, a shift has occurred toward more sophisticated treatment techniques that use multiple and often noncoplanar beams including three-dimensional and intensity-modulated radiation therapy. Attention has also been placed on accurate three-dimensional target delineated fields based on CT anatomy rather than only two-dimensional field design. In addition to refinements in radiation therapy target definition based on CT planning, technologic advances including study of and solutions for variability in target and normal organ location during a treatment course (day to day interfraction variability) and actual treatment delivered (intrafraction variability caused by respiration) have been undertaken. Interfraction variability in stomach location can be substantial, particularly among patients treated with neoadjuvant chemoradiation because of daily variations in gastric filling. Because of this, patients should generally be treated with an empty stomach. Intrafraction changes in target shape (deformation) and location are asymmetric and mainly from respiratory motion. Movement, particularly in the cranial-caudal dimension, frequently exceeds 1 to 1.5 cm. Image guidance, four-dimensional treatment planning, and respiratory gating have been developed to address these challenges.

More routine use of multiple field techniques should be considered when preoperative imaging exists to allow accurate reconstruction of target volumes. Single-institution data suggest that multiple field arrangements may produce less toxicity.³⁵⁴ Although AP/PA fields can be weighted anteriorly to keep the spinal cord dose at acceptable levels using only parallel-opposed techniques, a four-field technique, if feasible, can spare spinal cord radiation exposure, with improved dose homogeneity. Dependent on the posterior extent of the gastric fundus, either oblique or more routine lateral portals can be used to deliver a 10- to 20-Gy component of irradiation to spare the spinal cord or kidney. When lateral fields are used, liver and kidney tolerance limits the use of lateral fields to ≤ 20 Gy. With the wide availability of three-dimensional treatment-planning systems, it may be possible to target more accurately the high-risk volume, and to use unconventional field arrangements to produce superior dose distributions. To accomplish this without marginal misses, it will be necessary to both carefully define and encompass the various target volumes, given that the use of oblique or noncoplanar beams could potentially exclude target volumes that would be included in AP/PA fields or nonoblique four-field techniques (AP/PA and laterals). In most patients, a portion of both kidneys are within the treatment field, but at least two-thirds to three-fourths of one kidney should be excluded beyond a dose of 20 Gy. For proximal gastric lesions, $\geq 50\%$ of the left kidney is commonly within the irradiation portal, and

the right kidney must be appropriately spared. For distal lesions with narrow or positive duodenal margins, a similar amount of right kidney often is included, and every effort must be taken to spare the left kidney from irradiation in order to maintain function. Late renal sequelae have not been encountered with these techniques, assuming normal renal function bilaterally.³⁵⁵⁻³⁵⁷

With proximal gastric lesions or lesions at the EGJ, a 3- to 5-cm margin of distal esophagus should be included. If the lesion extends through the entire gastric wall, a major portion of the left hemidiaphragm should be included. In these circumstances, blocking can decrease the volume of irradiated heart.

TREATMENT OF ADVANCED DISEASE (STAGE IV)

Treatment of Advanced Gastric Cancer: Palliative Systemic Chemotherapy

Chemotherapy Versus Best Supportive Care

The modest activity and substantial toxicity of cytotoxic chemotherapy has raised the question, Does palliative systemic therapy with available agents have clinical utility? That is, there was controversy as to whether a meaningful advantage is attained by early initiation of systemic therapy as opposed to providing best supportive care. Although this is a difficult hypothesis to test because of patient and physician preferences and biases, several random assignment trials were performed in the 1990s in patients with advanced incurable gastric cancer addressing this issue.

Wagner et al.³⁵⁸ performed a meta-analysis for the Cochrane collaboration. They included three random assignment trials involving a total of 184 patients in whom the study design was to initiate systemic chemotherapy plus best supportive care or to provide best supportive care alone. Median survival and OS were evaluated (Table 46.6). Patients receiving chemotherapy as part of their treatment had better OS than those receiving best supportive care only, with an overall HR of 0.39 (95% CI = 0.28 to 0.52). The median survival was improved from 4.3 months for best supportive care to approximately 11 months for chemotherapy. Note that

the median survival for patients receiving chemotherapy is consistent with several more recent trials. There was also a modest improvement in time to progression (TTP; 7 months for patients receiving chemotherapy versus 2.5 months for patients receiving best supportive care). Wagner et al.³⁵⁸ concluded that the evidence supporting initiating chemotherapy for patients with advanced incurable gastric cancer was convincing.

In a fourth trial, QOL was assessed. The average quality-adjusted survival for patients undergoing chemotherapy was superior to patients receiving best supportive care (6 months versus 12 months). Importantly, in those best supportive care trials that reported 2-year survival (≥ 24 months), only patients undergoing chemotherapy survived for that period of time. The 2-year survival rate was 5% to 14% for patients receiving combination chemotherapy versus 0% for patients receiving best supportive care. More recently, the preliminary results of a small study testing the use of single-agent chemotherapy versus best supportive care in patients who have already received chemotherapy were reported. Previously treated patients were randomly assigned to best supportive care or to single-agent irinotecan plus best supportive care. Although the study was initially powered to require 120 patients, accrual to this type of trial was difficult and a total of only 40 patients were eventually randomized. There was a modest improvement in OS, with median survival for those receiving irinotecan of 123 days, and median survival for those with best supportive care 73 days (HR = 2.85).³⁵⁹ These results are in concert with the earlier studies in previously untreated patients and indicate that systemic therapy has a modest but real and clinically meaningful effect on outcome. Many cytotoxic agents have been studied in patients with advanced gastric cancer; when used as single agents, modest activity has been identified for drugs from five different classes. More recently, targeted therapy has been tested. The following section summarizes the data for the use of systemic cytotoxic chemotherapy when given with palliative intent. An extensive discussion of older agents can be found in prior editions of this textbook.

Single-Agent Chemotherapy

For most drugs, a variety of doses and schedules have been studied. In the absence of comparative trials using the same agent with different doses and schedules, superiority of one regimen over the other cannot be assessed. Table 46.7 gives a listing of agents that have demonstrated at least modest activity in the treatment of gastric cancer and which are routinely employed as part of standard practice options. Drugs with little or no activity, especially if they were evaluated prior to 2000, are not included in this table.

5-FU is the parent fluorinated pyrimidine that has been the most extensively studied single agent in gastric cancer. An anti-metabolite, the drug has been used in a variety of schedules and doses in various epithelial malignancies of gastrointestinal origin. One method involved the use of rapid intravenous injections on a weekly basis, or daily for 5 consecutive days. In gastric cancer, continuous infusion 5-FU has been used more recently. During the 1990s, in several studies, 5-FU was the control arm of a random assignment trial or was studied as a single agent (with leucovorin) in a prospective phase 2 trial. This allowed an assessment using more modern criteria of activity. The studies from the 1990s suggest overall response rates of 10% to 20%, with a median duration of response, or TTP, of approximately 4 months. As is the case in other diseases, the major toxicities reported in gastric cancer for 5-FU are mucositis, diarrhea, or mild myelosuppression. Because continuous intravenous infusion schedules can be cumbersome, oral analogues of 5-FU have been studied in gastric cancer. Three oral drugs of this class have undergone study in gastric cancer. These are tegafur and uracil (UFT), S-1 (tegafur and two modulators, 5-chloro-2,4-dihydropyridine and potassium oxonate), and capecitabine (Xeloda, Hoffmann-La Roche, Basel, Switzerland). The data for these agents are also shown in Table 46.7. S-1 has been most extensively studied in Japan. Although a response rate to

UFT, tegafur and uracil; S-1, tegafur and two modulators, 5-chloro-2, 4-dihydropyridine and potassium oxonate.

From van De Velde CJH, Kelsen D, Minsky B. Gastric cancer: clinical management. In: Kelsen D, Daly JM, Kern SE, et al., eds. *Principles and Practice of Gastrointestinal Oncology*. 2nd ed. Philadelphia: Lippincott Williams & Wilkins; 2008, with permission.

single-agent S-1 of 44% to 54% was reported in Japanese patients, the response rate among European patients was substantially lower. Like capecitabine, S-1 is now undergoing study in combination with other agents, particularly cisplatin. UFT combines tegafur and uracil. In gastric cancer, a response rate of 28% was seen in Japanese patients. In a small European study, Okines et al.³⁶⁰ reported the results of a European Organisation for Research and Treatment of Cancer (EORTC) study combining UFT and leucovorin. A 16% response rate was seen in a group of 23 patients. Capecitabine has been tested in fewer single-agent studies in gastric cancer. The data available suggest similar activity as seen with other oral fluorinated pyrimidines. Capecitabine has recently been extensively studied in combination with cisplatin or oxaliplatin (see “The REAL-2 Trial”).

Platinum compounds are an important part of the treatment of gastric cancer. The parent analogue, cisplatin, was studied in the 1980s. In both previously treated and untreated patients, a response rate of approximately 15% was reported. The major toxicities for cisplatin are nausea and vomiting, peripheral neuropathy, ototoxicity, and nephropathy. The development of efficacious antiemetics has significantly improved control of nausea and vomiting. An analogue of cisplatin, carboplatin, has been less well studied in gastric cancer; it appears to have less activity in this disease, as compared to other epithelial malignancies. Most recently, oxaliplatin, a diamino cyclohexane extensively used in the treatment of colorectal cancer, was included as part of combination chemotherapy for gastric cancer. The data for combination therapy, including oxaliplatin and data from the REAL-2 trial, are shown later.

A third class of cytotoxic agents with activity in gastric cancer is the taxanes. Both paclitaxel and docetaxel have been studied as single agents in gastroesophageal cancers. Docetaxel has been more extensively studied than paclitaxel. De Cosimo et al.³⁶¹ reviewed trials in which docetaxel was used as single agent. Patients may have received prior treatment, and 262 patients were evaluable for

response. The overall response rate was 19%. The major toxicities were neutropenia, alopecia, and edema. Allergic reactions were seen in about 25% of patients. The most common dosing schedule for docetaxel is 100 mg/m² every 3 weeks. When reported, the median TTP while on docetaxel therapy was 6 months. A schedule using lower doses given once weekly has also been studied with similar activity. On the basis of a large randomized study comparing CF to docetaxel-cisplatin-5-FU (DCF), docetaxel was approved by the US Food and Drug Administration for the treatment of advanced gastric cancer. Paclitaxel has also been studied in gastric cancer, although in smaller numbers of patients, and has a similar degree of cytotoxic activity.

A fourth class of active agent is represented by irinotecan. It has been studied both as a single agent and in combination with other cytotoxic agents. When used alone, response rates of 15% to 25% have been reported in both previously treated and untreated patients with advanced gastric cancer. Wagner et al.³⁵⁸ reviewed the data for combinations, including irinotecan versus multidrug combinations not including irinotecan. They concluded that irinotecan-containing multidrug chemotherapy combinations had a modest survival benefit, which was not statistically significant, when compared with regimens not including irinotecan. The major toxicities of irinotecan are myelosuppression and diarrhea.

Anthracyclines also have activity in gastric cancer. Single-agent data from the 1960s and 1970s show a response rate for doxorubicin of 17%, and for epirubicin a similar response rate of approximately 19%. The anthracyclines have undergone more extensive study in combination chemotherapy for advanced gastric cancer.

Single-Agent Versus Combination Chemotherapy

The potential advantage of giving combination chemotherapy versus single-agent chemotherapy has been evaluated by Wagner et al.³⁵⁸ in an update of their original Cochrane review. They found that combination chemotherapy had a significant survival advantage when compared to single-agent chemotherapy (HR = 0.82; 95% CI = 0.74 to 0.90). The difference in average median survival, however, was modest: 8.3 months for combination chemotherapy versus 6.7 months for single-agent chemotherapy. In the updated analysis, a test for heterogeneity was not statistically significant; they concluded that this indicated that the results of the different studies were consistent. A secondary analysis for response rate and for TTP also favored combination chemotherapy. Not surprisingly, toxicity is higher when several agents are given together, although this was not statistically significant. Treatment-related mortality was only slightly higher (1.5%) for patients receiving combination chemotherapy versus 1.1% when single-agent chemotherapy was used.

They also evaluated the role of several different combinations of cytotoxic agents, including anthracyclines as part of combination chemotherapy. In this analysis, three studies with a total of 500 patients were included. Wagner et al.³⁵⁸ found that including anthracyclines in a CF combination had a modest survival advantage over CF alone (HR = 0.77; 95% CI = 0.62 to 0.95). A similar advantage to anthracyclines in combination was found when 5-FU-anthracycline combinations without cisplatin were studied. In contrast to anthracyclines, there was a more modest, albeit not statistically significant, benefit for irinotecan-containing combinations. Once again, there was a modest improvement in OS for docetaxel-containing regimens, but this did not reach statistical significance. The response rate as a secondary objective was 36% for docetaxel-containing regimens versus 31% for nondocetaxel-containing regimens (not statistically significant). Oral fluoropyrimidines when compared to intravenous fluoropyrimidine therapy also showed no significant difference in median OS. The meta-analysis is in concert with the results of the REAL-2 trial, which indicated noninferiority for oral capecitabine when compared to intravenous 5-FU. Similarly, oxaliplatin regimens were compared to cisplatin-containing regimens with modest superiority to oxaliplatin.

In summary, there are five classes of cytotoxic chemotherapy agents in which single agents have modest activity in gastric cancer. The response rates range from 10% to 25%, and the median duration of response is relatively short (4 to 6 months). As a result of the single-agent trials, 5-FU or capecitabine (or other oral fluoropyrimidines), cisplatin or oxaliplatin, docetaxel, and less commonly, paclitaxel, epirubicin, and irinotecan are the major components of conventional combination cytotoxic systemic chemotherapy regimens.

Like other malignancies, multidrug regimens using agents that have single-agent activity have been extensively studied in gastric cancer. This section will focus on phase 3 random assignment trials. For some combinations, only phase 2 data are available. The recent Cochrane review summarizing a comparison of different regimens including three-drug versus two-drug combinations has already been discussed.³⁵⁸

Cisplatin-Fluorouracil. One of the most widely used combination chemotherapy regimens in upper gastrointestinal tract malignancies, including gastric cancer, is the two-drug combination of CF. Although this regimen has been used for several decades, with a variety of doses and schedules employed, since 2000, several phase 3 random assignment trials have been performed in which CF was the control arm. This allowed an opportunity for an evaluation of the efficacy of this combination, in patients with advanced incurable gastric cancer, both in terms of response rate, PFS, and OS, using currently accepted criteria for efficacy and toxicity of treatment. Table 46.8 shows the data from six studies in which CF was the control arm.³⁶² The doses of cisplatin used were 80 to 100 mg/m² per course. 5-FU was given as a continuous 24-hour infusion from days 1 through 5 at a dose of 800 to 1,000 mg/m² per day. Cycles were usually given on an every 28-day basis. Efficacy outcomes were consistent across these trials. Response rates, PFS, and OS were quite similar. Major objective tumor regression was

reported in 20% to 30% of patients; complete clinical remission was very uncommon, however. The median TTP or PFS, depending on the study, ranged from 3.7 months to 4.1 months, with median survival ranging from 7.2 months to 8.6 months. Two-year survival was between 7% and 10%. CF was compared to a variety of other agents in these trials.

Vanhoefer et al.,³⁶³ reporting for EORTC, compared CF to methotrexate, 5-FU, and doxorubicin (FAMTX); a third group of patients received etoposide, leucovorin, and 5-FU combination. There was no significant difference in outcome among the three arms. A Japanese study (JC 09205) also had three systemic therapy arms.³⁶⁴ 5-FU was compared to CF, and to a third arm of uracil/tegafur plus mitomycin. In this study, there was no advantage for the two-drug combination of CF over 5-FU alone. The final results of the TAX315 trial have recently been published.³⁶⁵ The details of this study are described later. An advantage was seen for the DCF arm. The CF control arm results were similar to those seen in the earlier trials previously described. The two-drug combination of 5-FU plus irinotecan was compared to CF by Dank et al.³⁶⁶ CF was equivalent to irinotecan plus 5-FU. Kang et al.³⁶⁷ reported the results of the RCT comparison between CF versus cisplatin-capecitabine. This study was designed as a noninferiority trial with the hypothesis that capecitabine-cisplatin was not inferior to CF. The end point was PFS. The dose of cisplatin was slightly lower than in the studies described earlier (80 mg/m²). However, therapy was given on every-3-week basis; 316 patients were treated. The median PFS was 5 months for CF; median survival was 9.3 months. Ajani et al.³⁶⁸ reported the results of the FLAGS trial, which is described in more detail later. In this study involving 1,029 eligible patients, the control arm of CF had a median OS of 7.9 months.

In summary, the random assignment trials discussed previously indicate consistent data for efficacy (and toxicity) for the two-drug combination CF. The Japanese study raises the question as to whether there is a substantial clinical advantage to CF over

RR, recovery rate; TTP, time to progression; PFS, progression-free survival; EORTC, European Organisation for Research and Treatment of Cancer; C, cisplatin; F, fluorouracil; JCOG, Japan Clinical Oncology Group; E, epirubicin; FLAGS, Cisplatin/S-1 With Cisplatin/Infusional Fluorouracil in Advanced Gastric or Gastroesophageal Adenocarcinoma Study; REAL, Randomized Trial of EOC +/- Panitumumab for Advanced and Locally Advanced Esophagogastric Cancer. Modified from van De Velde CJH, Kelsen D, Minsky B. Gastric cancer: clinical management. In: Kelsen D, Daly JM, Kern SE, et al., eds. *Principles and Practice of Gastrointestinal Oncology*. 2nd ed. Philadelphia: Lippincott Williams & Wilkins; 2008, with permission.

5-FU alone, but the meta-analysis performed by Wagner et al.³⁵⁸ supports the use of combination over single-agent chemotherapy. Although still commonly used as a conventional standard of practice palliative treatment, the recent demonstration of modest superiority when docetaxel is added to CF (assuming that a more well-tolerated regimen using the three agents can be developed) as well as the noncomparative data using ECF, which is discussed later, suggest that CF may not be the most effective option for therapy in patients with advanced gastric cancer. The slight advantage in longer-term survival (2-year survival) in the TAX325 and in the irinotecan–5-FU–leucovorin (FOLFIRI) studies of 15% to 20%, as compared to 15% to 20% for ECF, suggests that at least some patients may have longer-term survival with newer regimens.

Although type and incidence of treatment-related toxicity is consistent across most CF trials and is generally tolerable, it can be severe on occasion. For example, in the EORTC trial, grade 3 or 4 neutropenia was seen in approximately one-third of patients; one-quarter of patients had grade 3 or 4 nausea or vomiting. Similarly, in the more recent TAX325 trial, overall grade 3 or 4 toxicity was seen in 75% of patients receiving CF; in the FLAGS trial, treatment-related mortality occurred in 4.9% of patients receiving CF. Some toxicity may be ameliorated by improved supportive care. For example, newer antiemetics such as aprepitant should improve control of severe nausea and vomiting. More widespread use of supportive cytokine agents may decrease the incidence of neutropenic fever. Nonetheless, it should be recognized that CF, using the doses and schedules described previously, is associated with substantial toxicity in some patients.

The use of oral fluoropyrimidines in place of intravenous 5-FU has been studied in several phase 3 trials, including that of Kang et al.³⁶⁷ described earlier, the REAL-2 trial, and the FLAGS trial comparing CF to cisplatin–S-1. In FLAGS trial, 1,029 patients received either cisplatin 100 mg/m² and 5-FU 1,000 mg/m² as a continuous 5-day infusion or a slightly lower dose of cisplatin plus oral S-1.³⁶⁸ Median OS was 8.6 months for patients receiving cisplatin plus S-1 versus 7.9 months in the CF arm, with less toxicity for the cisplatin–S-1 combination. These three trials indicate that oral fluoropyrimidine when given with a platinum compound is not inferior to intravenous 5-FU plus cisplatin.

Docetaxel, Cisplatin, and Fluorouracil. Van Cutsem et al.³⁶⁵ have reported the final results of a large-scale random assignment trial comparing the DCF combination to CF (the TAX325 trial). Previously untreated patients with advanced gastric cancer received either DCF (221 analyzable patients) or CF using the doses and schedules previously described (224 patients). The primary end point of the study was TTP and was powered to detect an increase in median TTP from 4 to 6 months. The two arms of the study were well balanced for prognostic factors, including weight loss, performance status, and extent of disease. The median TTP was 3.7 months for patients receiving CF and 5.6 months for those receiving DCF (HR = 1.47; $p = 0.0004$). As a secondary end point, survival was also modestly increased from 8.6 months for CF to 9.2 months for DCF. The 2-year survival rate, however, was increased greater than two-fold in the DCF treatment arm (2-year OS: 8.8% for CF and 18.4% for DCF). Another measure of efficacy favoring DCF was tumor response to treatment (37% for DCF and 25% for CF). Although this study indicated an advantage to the three-drug combination of DCF, toxicity was also increased and was very substantial. Eighty-one percent of all patients receiving DCF had at least one grade 3 or 4 nonhematologic toxicity, as well as substantially more hematologic toxicity. Of the patients receiving CF, 14% had neutropenic fever, as did 30% of patients receiving DCF. However, there was no difference in the treatment-related mortality rate for the two arms. This study led to the recent approval of docetaxel by the US Food and Drug Administration for the treatment of gastric cancer when given in association with CF.

Like epirubicin, docetaxel, when added to CF, has a modest improvement in efficacy. The very substantial toxicity seen with

the DCF regimen, however, has led to concerns regarding its general use. A number of studies have been performed using modifications of DCF to develop a more tolerable regimen. Several strategies have been pursued, most of which involve using somewhat lower doses of docetaxel and 5-FU, or modifications in the schedule as to duration of 5-FU infusion or timing of the cisplatin dose. The preliminary results of a phase 2 trial comparing one of these modified DCF regimens to the original DCF schedule indicate that modifications of the treatment schedule may decrease toxicity while maintaining treatment efficacy.³⁶⁹

Irinotecan Plus Fluorouracil-Leucovorin. A three-drug combination of FOLFIRI has been studied extensively in metastatic colorectal cancer. A random-assignment phase 2 study comparing FOLFIRI with cisplatin-irinotecan indicated a potential advantage for the FOLFIRI-type regimen.³⁷⁰ Therefore, a definitive phase 3 trial was performed with CF as the control arm.³⁶⁶ A total of 170 patients received irinotecan–5-FU and 163 received CF. The primary end point was TTP. The analysis allowed for a noninferiority comparison between the two arms. The study was reasonably well balanced for the usual prognostic indicators; approximately 20% of patients had EGJ tumors. There was no significant difference in the major objective response rate (32% for irinotecan–5-FU and 26% for CF) nor in median TTP (5 months for irinotecan–5-FU and 4.2 months for CF). Overall median survival was also similar between groups (9 months for irinotecan–5-FU and 8.7 months for CF). Time to treatment failure was 4 months versus 3.4 months for irinotecan–5-FU and CF, respectively ($p = 0.018$). Irinotecan–5-FU was better in terms of toxic deaths (0.6% versus 3%), discontinuation for toxicity (10% versus 22%), neutropenia, thrombocytopenia, and stomatitis but not diarrhea than CF. The investigator's final conclusion was that irinotecan–5-FU was not inferior to CF and was somewhat less toxic.

Epirubicin, Cisplatin, and Fluorouracil. English investigators have extensively studied the three-drug combination ECF. Two random-assignment phase 3 trials have compared the ECF with a noncisplatin-containing combination (FAMTX) or with a mitomycin-cisplatin–5-FU (MCF) combination.³⁷¹ In the first study, ECF was more effective than FAMTX both in terms of response rate and median OS (8.7 months versus 6.1 months). Two-year survival was also superior for the ECF combination (14% versus 5%). In the second study, Ross et al.³⁷¹ compared ECF with MCF. In this larger study, 574 patients were treated. The primary end point was 1-year survival. The overall objective response rates were similar between the two arms (ECF 50% and MCF 55%). Toxicity was tolerable, although myelosuppression was greater for the experimental MCF arm. There was a slightly improved median duration of survival for ECF (9.4 months versus 8.7 months) and for 1-year survival (40% for ECF and 32% for MCF). There was no significant difference in 2-year survival, which was approximately 15% for both arms. Several studies have demonstrated that a small percentage of patients with advanced unresectable gastric cancer actually survive 2 years. Data for the ECF regimen as the control arm of the REAL-2 trial are discussed later.

Cisplatin Plus Irinotecan. Cisplatin is a commonly used agent in gastric cancer, and irinotecan has been combined with this drug as well as with other agents. In single-arm phase 2 studies, response rates were encouraging and toxicity was tolerable with irinotecan-cisplatin. This observation led to a somewhat larger random-assignment phase 2 trial comparing irinotecan-cisplatin with the irinotecan–5-FU regimen previously described.³⁷⁰ Sixty-two patients received irinotecan–5-FU and 61 received irinotecan-cisplatin. The dose schedule used for the irinotecan-cisplatin arm was higher than that from earlier irinotecan-cisplatin regimens. In this study, the response rate was higher for irinotecan–5-FU than for irinotecan-cisplatin, as was the TTP. Although irinotecan-cisplatin in the dose and schedule used in the random-assignment

phase 2 trial previously described was less effective than irinotecan–5-FU, other investigators have pursued this regimen using different schedules. These studies have been performed in patients with esophageal, gastroesophageal, and gastric cancers. One irinotecan-cisplatin regimen was used with bevacizumab.³⁷²

Fluorouracil-Leucovorin-Oxaliplatin. As is the case for irinotecan-containing regimens, oxaliplatin plus 5-FU is a standard practice option for patients with both metastatic and locally advanced colon cancer. In part because of this data, 5-FU–leucovorin-oxaliplatin (FOLFOX) regimens have also been studied in gastric cancer. The toxicity spectrum is similar to that seen in patients with colorectal cancer, with the dose-limiting toxicity of peripheral neuropathy (oxaliplatin). Myelosuppression, mucositis, and diarrhea typical for 5-FU regimens were noted as well. Several FOLFOX phase 2 studies have now been reported in gastric cancer. Overall response rates of approximately 50% were observed, with median TTP of 5 to 6 months and median OS ranging from 10 to 12 months.³⁷³

The REAL-2 Trial

Partly on the basis of these studies, a phase 3 trial comparing an oxaliplatin-based regimen with cisplatin-containing combinations was performed. Cunningham et al.³⁷⁴ in the REAL-2 trial studied 1,002 patients who were randomized to one of four treatment groups: a control arm of ECF and three investigational arms. The central question in this study was: Can capecitabine be substituted for 5-FU and/or oxaliplatin substituted for cisplatin. The four arms were ECF, epirubicin-oxaliplatin–5-FU, epirubicin-cisplatin-capecitabine, and epirubicin-oxaliplatin-capecitabine (EOX). The four regimens are shown in Table 46.9. Patients were stratified for performance status and extent of disease. The primary end point was in OS. The study

was powered to show noninferiority for capecitabine compared with 5-FU and oxaliplatin compared with cisplatin. There were approximately 250 patients per arm. The study design was a two-by-two comparison. A total of 40% of patients had primary gastric cancer, and the remainder had either EGJ or esophageal cancers, with 10% of patients having squamous cell cancer of the esophagus. There was no difference in median OS between the arms (ECF 9.9 months, epirubicin-oxaliplatin–5-FU 9.3 months, epirubicin-cisplatin-capecitabine 9.9 months, and EOX 11.2 months). The 1-year OS was also similar and ranged from 38% to 47%, the best outcome evident with EOX and the lowest with the control arm of ECF. The authors concluded the oxaliplatin could be substituted for cisplatin, and capecitabine could be substituted for 5-FU in the palliative setting.

Al-Batran et al.³⁷⁵ reported the results of a trial comparing a FOLFOX regimen with 5-FU–leucovorin-cisplatin (FLP). A modified FOLFOX-6 schedule was used for the experimental arm. The FLP regimen used slightly lower doses of 5-FU and cisplatin (50 mg/m² every 2 weeks. The study was powered for superiority of FOLFOX over FLP. A total of 220 patients were randomized between the two arms. There was no significant difference in TTP ($p = 0.08$) and OS (10.7 fluorouracil 2,600 mg/m² via 24-hour infusion, leucovorin 200 mg/m², and oxaliplatin 85 mg/m² [FLO] every 2 weeks versus 8.8 [FLP] months). Although this study did not demonstrate superiority for oxaliplatin-containing regimens, it does support the results of the REAL-2 study for noninferiority comparing oxaliplatin and cisplatin. The FOLFOX regimen was slightly less toxic.

Finally, Kang et al.³⁶⁷ compared XP with CF. A total of 160 patients received XP and 156 patients received CF. The XP arm was not inferior, with a median PFS of 5.6 months versus 5 months for CF. OS was 10.5 months versus 9.3 months for XP versus CF (HR = 0.85; 95% CI = 0.64 to 1.13; $p = 0.008$ versus noninferiority margin of 1.25). The authors concluded that XP can be considered an effective alternative to CF.

It is of note that FOLFOX, FOLFIRI, and capecitabine-containing regimens are widely used in colorectal cancer. In metastatic colorectal cancer, the median TTP using these regimens is approximately 7 to 8 months and the median survival (even without the use of bevacizumab) is 20 to 24 months. The 1-year survival for patients with stage IV unresectable colon cancer is approximately 70%, and, using these regimens, 2-year survival approaches 40%. As shown earlier, the same regimens used in patients with gastric or EGJ tumors result in substantially shorter times to progression and significantly shorter median survivals. There are more classes of active cytotoxic agents with demonstrated activity in EGJ than there are for colorectal cancer. In upper gastrointestinal tract malignancies, oxaliplatin, cisplatin, 5-FU, irinotecan, capecitabine, taxane, and anthracyclines have at least modest single-agent activity, whereas the taxanes and anthracyclines are not active in colorectal cancer. These differences in efficacy outcomes suggest biologic differences between these malignancies, despite the histologic similarities (e.g., “intestinal-type” gastric cancers).

As is the case for other solid epithelial malignancies, an important area of investigation is the development of better pre-clinical models, such as murine models, and the identification of predictive and prognostic biomarkers, which may well be different between gastrointestinal tumors arising in the upper and lower gastrointestinal tract. On the other hand, using targeted therapies, predictive markers may be the same in different cancers; for example, overexpression or amplification of *HER2* is a predictive marker for the use of the monoclonal antibody trastuzumab in both breast and now gastric cancers. It is also possible that the use of another cytotoxic treatment regimen (second-line treatment) after progression of disease on the first treatment regimen in gastroesophageal cancers would lead to a similar outcome as seen in colorectal cancers. For example, in the REAL-2 trial, only 15% of patients received additional therapy at the time of progression of disease. The irinotecan versus best supportive care study described previously suggests that at least some patients will have a modest survival benefit to second-line treatment.

TABLE 46.9

REAL-2 Regimens

Drug	Dose (mg/m ²)	Day(s)	Week(s) ^a
ECF			
Epirubicin	50 mg/m ² IV	1	Every 3 wk
Cisplatin	60 mg/m ² IV	1	
PVI 5-FU	200 mg/m ² /d ^b	1	
EOF			
Epirubicin	50 mg/m ² IV	1	Every 3 wk
Oxaliplatin	130 mg/m ² IV	1	
PVI 5-FU	200 mg/m ² /d ^b	1	
ECX			
Epirubicin	50 mg/m ² IV	1	Every 3 wk
Cisplatin	60 mg/m ² IV	1	
Capecitabine	625 mg/m ² /BID	1	
EOX			
Epirubicin	50 mg/m ² IV	1	Every 3 wk
Oxaliplatin	130 mg/m ² IV	1	
Capecitabine	625 mg/m ² /BID	1	

REAL, Randomized Trial of EOC +/- Panitumumab for Advanced and Locally Advanced Esophagogastric Cancer; ECF, epirubicin-cisplatin-fluorouracil; PVI, protracted venous-infusion; 5-FU, 5-fluorouracil; EOF, epirubicin-oxaliplatin-5-FU; IV, intravenously; ECX, epirubicin-cisplatin-capecitabine; BID, twice a day; EOX, epirubicin-oxaliplatin-capecitabine.

^a Planned treatment duration 24 weeks (eight cycles).

^b PVI 5-FU delivered by central venous access catheter.

Modified from Cunningham D, Okines AF, Ashley S, et al. Capecitabine and oxaliplatin for advanced esophagogastric cancer. *N Engl J Med* 2008;358:36.

Second-Line Therapy

Despite numerous chemotherapy options, the majority of patients who progress on first-line therapy are currently not treated with second-line chemotherapy in the West. In several series, only 20% to 50% of patients received second-line treatment.^{376,377} Patients with gastric cancer often have numerous comorbidities and complications of their malignancy (i.e., failure to thrive with significant protein-calorie losses, peritoneal carcinomatosis with limited bowel function) that preclude the safe administration of second-line therapy. Alternatively, as many as 70% of patients from Japan and other parts of Asia receive second-line therapy. Recently, there have been two random assignment studies that demonstrate the benefits of second-line therapy.^{378,379}

In one study, previously treated patients were randomly assigned to best supportive care or to single-agent irinotecan plus best supportive care. Although the study was initially powered to require 120 patients, accrual to this type of trial was difficult and a total of only 40 patients were eventually randomized. Despite the small sample size, the investigators observed a significant improvement in the HR for death (HR = 0.48) with the administration of irinotecan ($p = 0.012$).³⁵⁹ In a more recent and larger Korean study, 201 patients were randomized to second-line chemotherapy (either irinotecan or docetaxel) after progression on CF therapy. These investigators confirm an improvement in median OS with chemotherapy from 3.8 months with best supportive care alone to 5.1 months with the addition of chemotherapy.³⁷⁹ Together, these studies definitely establish that patients with metastatic gastric cancer who have maintained their performance status should be considered for second-line palliative chemotherapy as a standard of practice.

A random assignment study was conducted in patients with advanced gastric cancer comparing paclitaxel and irinotecan in the refractory setting.³⁸⁰ In this study, 223 patients were randomly assigned to either cytotoxic drug, with no difference in OS observed (median OS 9.5 months with paclitaxel and 8.4 months with irinotecan; HR = 1.13; $p = 0.38$).

Targeted Therapy

The Epidermal Growth Factor Receptor Superfamily: Monoclonal Antibodies

Trastuzumab. Overexpression or amplification of *HER2* (*EGFR2*) occurs in approximately 20% of patients with gastric cancer; it varies with the subtype. A phase 3 study of trastuzumab plus chemotherapy versus chemotherapy alone was performed in patients with gastric cancer overexpressing *HER2*. The preliminary results of the ToGA trial have been recently reported.³⁸¹ Among 3,807 patients, 594 patients had *HER2*-positive gastric cancer. They were randomized to receive either CF or XP given every 3 weeks for six cycles, or the same chemotherapy plus trastuzumab. The median OS was 13.5 months for patients receiving trastuzumab plus chemotherapy versus 11.1 months for those receiving chemotherapy alone (HR = 0.74; $p = 0.0048$). The response rate was 47% for patients receiving trastuzumab plus chemotherapy versus 35% for those receiving chemotherapy alone. There was no significant difference in toxicity between treatment arms. Trastuzumab has been approved in Europe for *HER2*-positive gastric cancer. The ToGA trial used a *HER2* scoring system similar to that used in breast cancer. *HER2* was more likely to be positive in patients with EGJ tumors than in more distal tumors (33% versus 20%); patients with diffuse gastric cancer were much less likely to have an *HER2*-positive (6%) tumor.³⁸²

Cetuximab and Panitumumab. Cetuximab is an antibody against epidermal growth factor receptors. In a trial combining cetuximab plus weekly infusions of oxaliplatin and 5-FU, and DL-folinic acid, 46 patients with advanced gastric cancer were treated.

Toxicity was tolerable; the response rate was 56%; however, OS was 9.5 months. K-Ras mutations were rare.³⁸³

The Epidermal Growth Factor Receptor Superfamily: Tyrosine Kinase Inhibitors

Lapatinib. Lapatinib is the first dual inhibitor of *HER1* (*EGFR1*) and *HER2* (*EGFR2*). Two phase 2 trials have evaluated lapatinib monotherapy in patients with advanced gastric cancer. In one study, 3 of 46 patients had partial responses. In the second study, 21 patients with EGJ adenocarcinomas were treated without objective responses.

Gefitinib and Erlotinib. Both are epidermal growth factor receptor tyrosine kinase inhibitors. In a large study, a 9% response rate was seen for EGJ tumors versus no responses among patients with gastric cancer; other studies have failed to demonstrate activity even in EGJ tumors.

The Vascular Endothelial Growth Factor Superfamily: Monoclonal Antibodies

Bevacizumab. Bevacizumab is a humanized monoclonal antibody that binds the vascular endothelial growth factor ligand (*VEGF-A*). In gastric cancer, Shah et al.³⁷² reported on combining cisplatin plus irinotecan with bevacizumab (phase 2). Among 47 patients, the median TTP was 9.9 months. A second phase 2 study evaluating bevacizumab with DCF also showed promising activity, with median PFS of 12 months and median OS of 17 months.³⁸⁴ This trial demonstrated potential efficacy with acceptable toxicity; follow-up phase 2 trials also demonstrated acceptable toxicity.³⁸⁵ The AVAGAST multinational phase 3 trial comparing bevacizumab plus CP versus CP alone has now completed accrual.^{386,387} Results have been reported.³⁸⁸

In this phase 3 study, 774 patients were randomly assigned to XP ($n = 387$) or XP/bevacizumab ($n = 387$). The study did not meet the primary end point of improving OS (12.1 months with XP/bevacizumab versus 10.1 months with XP; $p = 0.1002$), but did demonstrate improvement in PFS (6.7 months versus 5.3 months; $p = 0.0037$) and overall response rates (46.0% versus 37.4%; $p = 0.0315$) with XP/bevacizumab versus XP alone, respectively.^{386,387} In this study, there was distinct geographic variation in which patients enrolled from Asia appeared not to have significant benefit from the addition of bevacizumab. These results support the concept of significant worldwide disease heterogeneity.

A biomarker evaluation was prospectively performed from the AVAGAST study, in which plasma samples were available from 92% of the study population and tissue samples were available from 94% of the study population.³⁸⁹ In this analysis, baseline plasma *VEGF-A* levels and tumor neuropilin-1 expression were identified as potential predictors of bevacizumab efficacy. Specifically, patients with high baseline plasma *VEGF-A* appeared to benefit from bevacizumab therapy (HR = 0.72; 95% CI = 0.57 to 0.93), and similarly, patients with low baseline expression of neuropilin-1 also showed a trend toward improved OS with bevacizumab (HR = 0.75; 95% CI = 0.59 to 0.97). These data, if validated, may provide important insights pertaining to the geographic heterogeneity observed with this international phase 3 study, and importantly, may identify a population of patients for whom bevacizumab would have substantial efficacy when combined with chemotherapy.

The Vascular Endothelial Growth Factor Superfamily: Tyrosine Kinase Inhibitors

Sunitinib. Sunitinib is an oral inhibitor of *VEGF* receptor [*VEGFR*]-1, -2, -3, and *PDGFR- α* , - β , and *c-kit*. Bang et al.³⁸⁹ reported on a phase 2 trial of sunitinib as second-line treatment for

advanced gastric cancer. Response rate, PFS, and OS were 2 of 72 patients, 11.1 weeks, and 47.7 weeks, respectively. Sorafenib is another multityrosine kinase inhibitor (VEGFR-2, -3; platelet-derived growth factor receptor- β ; Flt-3; Raf-1; and c-kit). The ECOG5203, a phase 2 trial investigating docetaxel plus cisplatin plus sorafenib in gastric cancer, suggested clinical efficacy (response rate = 39%; PFS = 5.8 months; OS = 15.9 months).³⁹⁰

Recently, a random assignment phase 2 study of apatinib, a tyrosine kinase inhibitor that selectively inhibits VEGFR2, appears to be active in advanced gastric cancer.³⁹¹ In this study, 144 patients were randomly assigned to placebo or two different doses of apatinib. Patients assigned to apatinib had a statistically significant improved OS (4.83 and 4.27 months in the apatinib arms versus 2.5 months in the placebo; $p = 0.0017$), with nine patients demonstrating a radiographic partial response.

In addition, a second study has demonstrated efficacy of VEGFR2 inhibition as monotherapy in gastric cancer. Ramucirumab (IMC-1121B) is a fully human IgG1 monoclonal antibody targeting VEGFR-2. The REGARD study was a placebo-controlled, double blind, phase 3 international trial conducted in the second-line setting in patients with metastatic gastric or EGJ adenocarcinoma. Median OS was 5.2 months for ramucirumab and 3.8 months for placebo (HR = 0.776; 95% CI = 0.603 to 0.998; $p = 0.0473$). The significance of this study is that it provides a proof-of-principle that antiangiogenic therapy does have activity in gastroesophageal malignancies. The REGARD study supports the concept that subtypes of gastric cancer exist and may be differentially sensitive to antiangiogenic therapy.³⁹²

Inhibition of Mammalian Target of Rapamycin (Protein Kinase)

Everolimus. An oral inhibitor of the mammalian target of rapamycin has shown activity against gastric cancer in preclinical phase 1 studies.^{393,394} Doi et al.³⁹⁴ reported on a phase 2 trial testing everolimus in metastatic gastric cancer. In 53 patients, the disease control rate (complete response rate plus partial response plus stable disease) was 56%, and the median PFS and OS were 2.7 and 10.1 months, respectively. Based on these encouraging results, a phase 3 study was performed comparing everolimus to best supportive care.³⁹⁵ In this study, 656 patients were randomized in a 2:1 fashion to everolimus versus placebo. Median OS was similar in both arms, 5.4 months versus 3.2 months (HR = 0.9; 95% CI = 0.75 to 1.08; $p = 0.12$).

In summary, new agents targeting dysregulated cancer pathways are now undergoing study in gastric cancer. At the present time, trastuzumab remains the only drug of this type that has demonstrated efficacy, in combination with cytotoxic chemotherapy, in gastric cancer.

Predictive Markers and Early Assessment of Response in Gastric and Gastroesophageal Tumors

The recognition that several different classes of cytotoxic anticancer agents and targeted pathway agents have activity in subgroups of patients suggests the possibility that predictive markers or a gene signature might allow “customized” precision cancer care that will spare patients from unnecessary toxicity from ineffective therapy, such as testing for *HER2* identifies patients who could benefit from trastuzumab. Molecular markers that might indicate resistance or sensitivity to CF are reviewed elsewhere in this book.³⁹⁶ Ooi et al.³⁹⁶ and other investigators^{397–399} have used gene expression arrays to identify pathways and gene signatures to predicting clinical prognosis. Ott et al.⁷⁷ reported that a drop in SUV of 35% after neoadjuvant chemotherapy was associated with significant pathologic response to systemic treatment. Similar findings were reported by Shah et al.⁴⁰⁰ and Weber.⁴⁰¹ Overall, PET may allow early identification of patients responding to systemic therapy.

SURGERY IN TREATMENT OF METASTATIC GASTRIC CANCER

Given the recent improvements in systemic therapy for gastric cancer, the question whether resection of limited metastases from gastric cancer can provide survival benefit remains unanswered. To ask this question in a scientific manner, the surgery branch of the National Institutes of Health/National Cancer Institute is currently accruing patients to a prospective RCT comparing gastrectomy, metastasectomy plus systemic therapy, versus systemic therapy alone (the GYMSSA Trial, clinicaltrials.gov no. NCT00941655).⁴⁰²

The GYMSSA trial randomized patients with metastatic gastric cancer to gastrectomy, cytoreductive surgery (CRS)/HIPEC plus Folfoxiri (GYMS arm) versus Folfoxiri alone (SA arm) to study OS. All patients underwent comprehensive staging including laparoscopy. To date, the study accrued 16 evaluable patients. Seven of nine patients in the multimodality GYMS arm achieved complete cytoreduction, with median follow-up of 23 months. Median OS was 12 months in the GYMS arm and 10.2 months in the SA arm; 1- and 2-year OS was 44% and 22% versus 0% and 0%, respectively. Two patients in the GYMS arm lived beyond 23 months, and one up to 12 months. No patient in the SA arm lived longer than 12 months.

Kerker et al.^{401,402} reviewed the published data reporting on liver resection for gastric cancer; 19 studies reported on 436 patients. The majority of the patients had synchronous isolated liver gastric metastases. Overall, the 1-, 3-, and 5-year survival rates were 62%, 30%, and 27%, respectively; 13% (48/358) were alive at 5 years, and in studies with >10 years of follow-up, 4% (48/358) survived for >10 years.⁴⁰²

Standard of care for patients with pulmonary gastric metastases is chemotherapy with a median survival of 6 months.⁴⁰³ Kemp et al.⁴⁰³ reviewed the published data reporting on lung resections for gastric cancer; 21 studies reported on 43 patients. Eighty-two percent of patients (34/43) had a solitary lesion. At a median follow-up of 23 months, 15 of 43 (35%) patients had no evidence of disease. The overall 5-year survival was 33%.

Gastric carcinomatosis occurs in 5% to 50% of patients undergoing surgery with curative intent.^{404–410} The median survival for such patients is 1.5 months to 3.1 months.^{404,411–413} Overall data are limited; however, several investigators reported on CRS plus HIPEC for gastric carcinomatosis; the median OS ranged from 6 to 21 months, and 5-year survival ranged from 6% to 16% with operative mortality of 2% to 7% mortality. In patients with optimal cytoreduction-CCR-0/1 (no macroscopic or disease <5 mm), the 5-year survival was 16% to 30%. Complete cytoreduction was possible in only 44% to 51% of the patients.^{309,414–418} In 2008, the Fifth International Workshop on Peritoneal Surface Malignancy indicated that peritonectomy, intraoperative, and early postoperative HIPEC potentially can be a powerful therapy against gastric cancer peritoneal carcinomatosis.^{419–424}

Bidirectional chemotherapy utilizing intraperitoneal and systemic induction chemotherapy prior to CRS and HIPEC has been studied (retrospectively) in patients with peritoneal carcinomatosis of gastric origin undergoing treatment in a specialized peritoneal surface malignancy unit in Japan. A recent study of 194 patients with gastric carcinomatosis treated initially and responsive (response rate 78%) to intraperitoneal docetaxel (20 mg/m²) and cisplatin (30 mg/m²) followed by four cycles of oral S-1 (60 mg/m²), followed by CRS/HIPEC reported median OS of 16 months and 1-, 2-, and 5-year survival of 66%, 32%, and 11%, respectively.⁴²⁵ Operative morbidity and mortality were 24% and 4%, respectively. Response to bidirectional intraperitoneal and systemic chemotherapy, low tumor burden (peritoneal cancer index ≤ 6) and completeness of cytoreduction (CCR0/1) were independently associated with improved OS on multivariate analysis.

Surgery for Palliation

Because survival for patients with advanced gastric cancer is poor, any proposed operation could have a good chance of providing sustained symptomatic relief while minimizing the attendant morbidity and need for prolonged hospitalization. Ekbohm and Gleysteen⁴²⁶ have reviewed the results of palliative resection versus intestinal bypass (gastrojejunostomy) in 75 patients with advanced gastric cancer. The most frequent symptoms for which patients underwent operation included pain, hemorrhage, nausea, dysphasia, or obstruction. Operative mortality was 25% for gastrojejunostomy, 20% for palliative partial or subtotal gastrectomy, and 27% for total or proximal palliative gastrectomy. The most common and often fatal complication was anastomotic leak. After gastrojejunostomy, 80% of patients had relief of symptoms for a mean of 5.9 months compared with palliative resection, which provided relief of symptoms in 88% of patients for a mean of 14.6 months. Although the duration of palliation was significantly longer after resection ($p < 0.01$), the selection criteria for resection versus bypass were not controlled, and some bias against performing a palliative resection in high-risk patients with more advanced disease may have occurred. Meijer et al.⁴²⁷ also reported on a retrospective analysis of 51 patients undergoing either palliative intestinal bypass or resection. In 20 of 26 patients (77%) undergoing resection, palliation was considered moderate to good with a mean survival of 9.5 months. After gastroenterostomy, some palliation was noted in 8 of 25 patients (30%), and survival was 4.2 months. Butler et al.⁴²⁸ have presented the results of total gastrectomy for palliation in 27 patients with advanced gastric cancer. Operative mortality was only 4%, whereas morbidity occurred in 48% of patients. Median survival was 15 months, with a survival rate of 38% at 2 years. This substantial survival rate at 2 years reflects that, although all patients were symptomatic before surgery, only half had stage IV disease. Patients with linitis plastica present a very difficult therapeutic challenge. Resection may provide palliation of symptoms;

however, survival after total gastrectomy is exceedingly poor, ranging from 3 months to 1 year.

Bozzetti et al.^{429,430} have reviewed the outcomes of 246 patients with advanced gastric cancer who underwent simple exploratory laparotomy alone, gastrointestinal bypass, or palliative resection at the National Cancer Institute of Milan. When survival was compared in patients with similar type and extent of disease, a consistent trend was seen for improved median OS with palliative resection in patients with local spread (4 months versus 8 months) and distant spread of disease (3 months versus 8 months). Boddie et al.⁴³¹ have reported similar results in 45 patients undergoing palliative resection at the MD Anderson Cancer Center for advanced gastric cancer. Operative mortality for resection was 22%. In 21 patients who had undergone a palliative bypass procedure, OS was significantly shorter than for those undergoing palliative gastric resection ($p < 0.01$).

In select patients with symptomatic advanced gastric cancer, resection of the primary disease appears to provide symptomatic relief with acceptable morbidity and mortality, even in the presence of macroscopic residual disease.

RADIATION FOR PALLIATION

To date, no studies have evaluated the use of radiation therapy in patients with locally recurrent or metastatic carcinoma of the stomach. Its use is likely to be limited to palliation of symptoms such as bleeding or controlling pain secondary to local tumor infiltration. Although minimal data are available, radiation therapy seems to be anecdotally effective in controlling bleeding, as is true in other primary tumor sites. Pain from local tumor invasion can also be palliated with radiation. On rare occasions, a case may arise of a patient with a focal local recurrence without metastases who would be amenable to relatively high-dose radiation therapy in order to try to prolong quality-adjusted survival or in whom radiation therapy would be given as an adjuvant to surgical resection. At present, however, no data support such an approach.

47 Genetic Testing in Stomach Cancer

Nicki Chun and James M. Ford

INTRODUCTION

Gastric cancer encompasses a heterogeneous collection of etiologic and histologic subtypes associated with a variety of known and unknown environmental and genetic factors. It is a global public health concern, accounting for 700,000 annual deaths worldwide, and currently ranks as the fourth leading cause of cancer mortality, with a 5-year survival of only 20%. The incidence and prevalence of gastric cancer vary widely, with Asian/Pacific regions bearing the highest rates of disease.

Recent and rapid advances in molecular genetics have provided an understanding of the cause for many inherited cancer syndromes, offering possibilities for individual genetic testing, family counseling, and preventive approaches. For most cancer syndromes, however, not every individual tested is found to have inherited a germ-line mutation in a candidate gene, suggesting additional uncharacterized alterations in other genes that result in similar outcomes. Nevertheless, the ability to genetically define many individuals and families with inherited cancer syndromes allows for a multidisciplinary approach to their management, often including the consideration of surgical and medical preventive measures. Without question, such complex management and decision making should be centered in the high-risk cancer genetics clinic, where physicians, genetic counselors, and other health professionals jointly consider optimal management for patients and families at high risk for developing cancer.

Approximately 3% to 5% of gastric cancers are associated with a hereditary predisposition, including a variety of Mendelian genetic conditions and complex genetic traits. Identifying those gastric cancers associated with an inherited cancer risk syndrome is the purview of cancer genetics clinics. The keystone to any cancer genetics evaluation is a complete, three-generation family history. Pedigree analyses suggesting an inherited gastric cancer risk include familiar features such as multiple affected relatives tracking along one branch of the family in an autosomal-dominant pattern, young ages at onset, and additional associated malignancies related to an identified syndrome. It is imperative to document the histology of the gastric tumors and other familial cancers because this is the initial node in the decision tree of an inherited gastric cancer syndrome differential. Finally, there are clinical criteria for recognized gastric cancer syndromes published by expert consensus panels that assist genetic practitioners in assessing both the likelihood of identifying an underlying germ-line DNA mutation and guide management in the absence of a molecular confirmation. Herein, we review the literature regarding incidence, recurrence risks, and defined gastric cancer genetic syndromes to assist in providing genetic counseling for families affected by gastric cancer.

HISTOLOGIC DEFINITIONS AND DESCRIPTIONS

Gastric cancer has traditionally been subtyped pathologically according to Lauren's¹ classification published in 1965 and revised by Carneiro et al.² in 1995. The four histologic categories

include: (1) glandular/intestinal, (2) border foveal hyperplasia, (3) mixed intestinal/diffuse, and (4) solid/undifferentiated.

More clinically relevant, the majority of gastric cancers can be subdivided into intestinal type or diffuse type. Diffuse tumors exhibit isolated cells that typically develop below the mucosal lining and often spread and thicken until the stomach appears hardened into the morphologic designation called *linitis plastica*. Diffuse gastric tumors frequently feature *signet ring cells*, named for the marginalization of the nucleus to the cell periphery due to high mucin content. Intestinal-type gastric tumors more often present as solid masses with atrophic gastritis and intestinal metaplasia at the periphery. The intestinal subtype is seen more commonly in older patients, whereas the diffuse type affects younger patients and has a more aggressive clinical course. The relative proportions of gastric cancer subtypes worldwide are 74% intestinal versus 16% diffuse and 10% other,³ although diffuse gastric cancer is becoming relatively more common in Western countries. The importance of distinguishing these two main histopathologic types of gastric cancer is highlighted by finding specific genetic changes associated with the different types. For the purposes of genetic counseling, E-cadherin (*CDH1*) mutations are found exclusively in the diffuse type.⁴⁻⁸ Whereas intestinal-type hereditary gastric cancer families have been identified clinically, no genetic associations have yet been discovered.

As individual molecular profiling of solid tumors becomes more common in the future, we expect classification systems will evolve based on tumor biology more than histology. Advances in deciphering the mechanisms of gene alterations that lead to gastric cancer include gene mutation, amplification, deletion, and epigenetic methylation.⁹ For example, two recent studies have performed whole-exome sequencing of human gastric tumors and identified a number of known (e.g., *p53*, *PTEN*, *PIK3CA*), but also previously unreported somatic gene mutations and pathway alterations. Both found *ARID1A* inactivating gene mutations in the majority of microsatellite-unstable tumors, a member of the SWI-SNF chromatin remodeling family.^{10,11} However, whether any of these somatic gene alterations are found to confer cancer risk when mutated in the germ line remains to be determined.

ETIOLOGY

Analogous to other common cancers, a host of factors are implicated as causes of gastric cancer. Widely diverse geographical disparities suggest both environmental and genetic contributions. Furthermore, a strong association with endemic *Helicobacter pylori* carrier rates implicates infection as a major risk factor. There are likely to be a host of factors contributing to the development of most gastric cancers.

Environmental Risk Factors

Geographic variations in gastric cancer rates have prompted investigations of shared diet and lifestyle variables. Gastric cancer is correlated with the chronic ingestion of pickled vegetables, salted fish, excessive dietary salt, smoked meats, and with smoking.¹²⁻¹⁶

Fruits and vegetables may have a protective effect. The influence of environmental factors as causes of gastric cancer is highlighted by declining rates of intestinal gastric cancer among immigrants from high-incident countries to low-incident countries.

Infectious Risk Factors

H. pylori infection is endemic in the Asian–Pacific basin.¹⁷ Transmission routinely occurs through family contacts in childhood and leads to atrophic gastritis.^{18,19} As evidenced by high indigenous infection rates, *H. pylori* is insufficient to singularly cause gastric cancer, suggesting complex interactions between virus and host genetic backgrounds. However, *H. pylori* species are consistently implicated as a major risk factor primarily associated with intestinal-type gastric cancer. Studies in a variety of high- and low-risk populations have found odds ratios ranging from 2.56 to 6 for noncardia gastric cancer.²⁰

The Epstein-Barr virus has recently been implicated in about 10% of gastric carcinoma worldwide, or an estimated 80,000 cases annually. Epstein-Barr virus–associated gastric cancer shows some distinct clinicopathologic characteristics, such as male predominance, predisposition to the proximal stomach, and a high proportion in diffuse-type gastric carcinomas. Mechanistically, Epstein-Barr virus gastric tumors display epigenetic promoter methylation of many cancer-related genes, causing downregulation of their expression.²¹

Genetics

Five to 10% of gastric cancer is associated with strong familial clustering and attributable to genetic factors. Shared environmental factors account for the majority of familial clustering of the intestinal type; however, approximately 5% of the total gastric cancer burden is thought to be due to germ-line mutations in genes causing highly penetrant, autosomal-dominant gastric cancer risk of both intestinal and diffuse subtypes. We review the definitions of hereditary gastric cancer families and recognize genetic syndromes associated with increased gastric cancer risk.

EPIDEMIOLOGY OF GASTRIC CANCER

Gastric cancer is now the fourth most common malignancy worldwide, with rates having fallen steadily since 1975 when global statistics were first compared. The incidence and prevalence of gastric cancer vary widely among world populations. High-risk countries (reported incidence \times 100,000 per year) include Korea (41.4), China (41.3), Japan (31.1), Portugal (34.4), and Colombia (20.3). Intermediate-risk countries include Malaysia, Singapore, and Taiwan (11 to 19, respectively), whereas low-risk areas include Thailand (8), Northern Europe (5.6), Australia (5.4), India (5.3), and North America (4.3). More than 70% of cases occur in developing countries, and men have roughly twice the risk of women.²² In 2008, estimates of gastric cancer burden in the United States were 21,500 cases (13,190 men and 8,310 women) and 10,880 deaths.²³ The median age at diagnosis for gastric cancer is 71 years, and 5-year survival is approximately 25%.²⁴ Only 24% of stomach cancers are localized at the time of diagnosis, 30% have lymph node involvement, and another 30% have metastatic disease. Survival rates are predictably higher for those with localized disease, with corresponding 5-year survival rates of 60%.

The worldwide decline in the incidence of gastric cancer has been attributed to modifications in diet, improved food storage and preservation, and decreased *H. pylori* infection. Fresh fruit and vegetable consumption, refrigeration, decreased urban crowding, and improved living conditions have reduced *H. pylori* exposure and carrier rates. By contrast, the incidence of diffuse-type gastric cancer is stable, and in North America, it may even be increasing.^{16,25–27}

TABLE 47.1

Clinical Criteria for CDH1 Testing Defined by the 2010 International Gastric Cancer Linkage Consortium

1. Two gastric cancer cases in the family: one confirmed diffuse type and one diagnosed at the age of <50 y
2. Three confirmed diffuse gastric cancers in first- or second-degree relatives independent of age
3. Diffuse gastric cancer diagnosed at age <40 y (no additional family history needed)
4. Personal or family history (first- or second-degree) of diffuse gastric cancer and lobular breast cancer, one diagnosed at age <50 y

From Fitzgerald RC, Hardwick R, Huntsman D, et al. Hereditary diffuse gastric cancer: Updated consensus guidelines for clinical management and directions for future research. *J Med Genet* 2010;47:436–444.

Familial Gastric Cancer

Shared environmental factors, such as diet and *H. pylori* infection, account for the majority of familial clustering of the intestinal type of gastric cancer, with no known causative germ-line variants. However, few nongenetic risks for diffuse gastric cancer have been identified, supporting a larger role for hereditary factors. Approximately 5% of the total gastric cancer burden is thought to be due to germ-line mutations in genes causing a highly penetrant, autosomal-dominant predisposition. The International Gastric Cancer Linkage Consortium (IGCLC) has redefined genetic classification of familial intestinal gastric cancer to reflect the background incidence rate in a population (Table 47.1).

Thus, countries with high incidence of intestinal-type gastric cancer (China, Korea, Japan, Portugal) use criteria analogous to the Amsterdam criteria invoked for Lynch syndrome:

- At least three relatives with intestinal gastric cancer, one a first-degree relative of the other two
- At least two successive generations affected, and
- Gastric cancer diagnosed before the age of 50 years in at least one individual

In countries with a low incidence of intestinal-type gastric cancer (United States, United Kingdom):

- At least two first-/second-degree relatives affected by intestinal gastric cancer, one diagnosed before the age of 50 years, or
- Three or more relatives with intestinal gastric cancer at any age

Familial intestinal gastric cancer families are similarly prevalent as familial diffuse gastric cancer families, yet a germ-line genetic defect underlying the disease remains to be identified.²⁸ Hemminki et al.²⁹ reported Swedish data on all available types of cancer in first-degree relatives by both parent and sibling probands. The relative risks (RR) for gastric cancer were greater than 3 for siblings with any relative with gastric cancer and greater than 5 when a sibling was younger than 50 years. Shin et al.³⁰ assessed 428 gastric cancer subjects and 368 controls in Korea for the risk of gastric cancer in first-degree relatives and found an RR of 2.85 with one first-degree relative and greater than 5 in a first-degree relative with *H. pylori* and a positive family history. Therefore, in the high-incident countries of Japan and Taiwan, population screening for gastric cancer has greatly enhanced early detection, leading to 5-year survival rates of greater than 90%.³¹

Hereditary Diffuse Gastric Cancer

In 1999, the first IGCLC defined hereditary diffuse gastric cancer (HDGC) as families with (1) two cases diffuse gastric cancer in first-/second-degree relatives with one younger than 50 years, and

(2) three cases diffuse gastric cancer at any age.³² The first clear evidence for a gastric cancer susceptibility genetic locus was the identification in 1998 of a germ-line inactivating mutation in the gene encoding for E-cadherin (*CDH1*) in a large, five-generation Maori family from New Zealand with 25 kindred with early-onset diffuse gastric cancer.³³ The age at diagnosis of gastric cancer ranged upward from 14 years, with the majority occurring in individuals younger than 40 years. The pattern of inheritance of gastric cancer was consistent with an autosomal-dominant susceptibility gene with incomplete penetrance. Similar reports of *CDH1* mutations in widely diverse HDGC cohorts from Asia, Europe, and North America followed soon thereafter.^{34–39} Germ-line *CDH1* mutations have been found to be associated with approximately 30% of families with HDGC, with a lifetime risk for gastric cancer of greater than 80%, and up to 60% risk for female carriers developing lobular breast cancer.⁴⁰ To date, *CDH1* is the only gene implicated in HDGC. Worldwide, about 100 *CDH1* mutation-positive families have been reported.⁴¹

E-cadherin Mutations and Gastric Cancer

The E-cadherin gene coding sequence gives rise to a mature protein consisting of three major domains, a large extracellular domain (exons 4 to 13), smaller transmembranes (exons 13 to 14), and cytoplasmic domains (exons 14 to 16). As in other autosomal-dominant cancer predisposing genes, only one *CDH1* allele is mutated in the germ line, and the majority of genetic changes lead to truncation of the protein, with mutations distributed throughout the gene's 2.6 kb of coding sequence and 16 exons without any apparent hotspots. Somatic *CDH1* mutations have been identified in about half of sporadic diffuse gastric cancers, but occur rarely in intestinal gastric cancer. *CDH1* encodes the calcium-dependent cell-adhesion glycoprotein E-cadherin. E-cadherin is a transmembrane protein that connects to the actin cytoskeleton through a complex with catenin proteins.^{5,42} Functionally, E-cadherin impacts the maintenance of normal tissue morphology and cellular differentiation. With regard to HDGC, it is believed that *CDH1* acts as a tumor suppressor gene, with the mutation of *CDH1* leading to a loss of cell adhesion, proliferation, invasion, and metastasis.⁴³

Genetic Testing for HDGC

At the second meeting of the IGCLC in 2010, HDGC guidelines⁴⁴ were extended to recommend *CDH1* genetic testing to families with the following:

- Cases of gastric cancer in which one case is histopathologically confirmed as diffuse and younger than 50 years
- Families with both lobular breast cancer and diffuse gastric cancer, with one diagnosed younger than 50 years
- Proband diagnosed with diffuse gastric cancer younger than 40 years, with no family history of gastric cancer

Using the initial IGCLC criteria for HDGC, *CDH1* mutation testing yielded a detection rate of 30% to 50%.⁴⁵ Interestingly, a pattern began to emerge of lower *CDH1* mutation rates among HDGC families in high gastric cancer incidence populations and higher rates in low-incident countries.^{46,47} Other reports suggest that the rate of *CDH1* mutations in isolated cases of diffuse gastric cancer younger than 35 years is similar in both low- and high-risk countries, hovering at around 20%.⁴⁸

Approximately 50% to 70% of clinically diagnosed HDGC families have no identifiable genetic mutation. Multiple candidate loci have been investigated without identifying causative mutations that would account for the large number of non-*CDH1* HDGC families.^{49–51} Huntsman's group has published a report of multiplex ligation-dependent probe amplification-based exon duplication/deletion studies performed on 93 non-*CDH1* families

and found 6.5% carried large genomic deletions, bringing the detection rate up to 45.6% in their cohort of 160 families.⁵²

As *CDH1* mutation families were identified, data on these families provided the foundation for genetic counseling information. Initially, the cumulative risk of gastric cancer by the age of 80 years in HDGC families was initially estimated as 67% for men and 83% for women. The age at onset shows marked variation between and within families. The median age at onset in the 30 Maori *CDH1* mutation carriers who developed gastric cancer was 32 years, which was significantly younger than the median age of 43 years in individuals with gastric cancer from other ethnicities.⁵³ More recent reports of the lifetime risks of diffuse gastric cancer suggest greater than 80% in both men and women by the age of 80 years.^{48,54}

The lifetime risk for lobular breast cancer among female *CDH1* carriers, originally estimated to be in the range of 20% to 40%, now approaches 60%, with an average age of 53 years at the time of diagnosis.^{36,54,55} Of note, *CDH1* mutations have been seen in up to 50% of sporadic lobular breast cancer. Pathologic similarities between diffuse gastric and lobular breast carcinomas such as high mucin content with associated signet ring features and loss of E-cadherin on immunohistochemistry hint at a common molecular mechanism.^{56,57} To evaluate the *CDH1* carrier rate in women with lobular breast cancer without a family history of diffuse gastric cancer, a multicenter study of 318 women with lobular-type breast cancer diagnosed before the age of 45 years and known to be BRCA1/2-negative were sequenced for *CDH1* mutations. Only four possibly pathogenic mutations were identified for a rate of 1.3%, suggesting *CDH1* is a rare cause of early lobular cancer without associated gastric cancer family history.⁵⁸

Signet ring colon cancer has been reported in two families with germ-line *CDH1*, but no screening guidelines have been suggested.^{45,59} Nonsyndromic cleft lip and/or palate was reported in seven individuals from three families in the Netherlands and in four individuals from two families in France. There is speculation that defects in the cell-adhesion role of E-cadherin may contribute to this developmental anomaly, although no association can be drawn from these scant case reports.^{40,60}

Like other familial cancer syndromes with an autosomal-dominant inheritance pattern, high penetrance for heterozygotes, and significant mortality unless diagnosed early, genetic counseling and testing should occur early, and a comprehensive screening plan should be developed, as well as the consideration of prophylactic surgery. Pretest and posttest genetic counseling should be provided to individuals from HDGC kindred who are undergoing genetic testing for germ-line *CDH1* mutations. Because cases of gastric cancer in HDGC families have been reported in individuals as young as 14 years, HDGC may be considered one of the sets of hereditary cancer syndromes, such as MEN 2-associated medullary thyroid cancer, Li-Fraumeni syndrome (LFS), and familial adenomatous polyposis (FAP), in which genetic testing is potentially clinically useful in children.

SCREENING AND MANAGEMENT OF CANCER RISK IN HDGC

Diagnosing gastric cancer in its early stages provides the best chance for curative resection but is a difficult task. Symptoms due to gastric cancer are generally nonspecific and do not appear until the disease is more advanced. The survival of early gastric cancer (e.g., not beyond the mucosa or submucosa) is much better than advanced lesions, so identifying these lesions at the earliest of stages is imperative for optimal survival. Endoscopy is generally considered to be the best method to screen for gastric cancer, but diagnosing diffuse gastric carcinoma is most difficult, because these lesions tend not to form a grossly visible exophytic mass, but rather spread submucosally as single cells or clustered islands of cells. Improved chromoendoscopic-aided methods for directed

biopsies to diagnose these early diffuse lesions may prove beneficial, but so far all approaches at screening, including computed tomography and positron emission tomography imaging, have proven disappointing.⁶¹

Given the inadequacy of clinical screening in HDGC, prophylactic total gastrectomy is offered to carriers of germ-line *CDH1* mutations.^{62,63} In every published series of this approach, nearly all specimens contain multiple foci of intramucosal diffuse signet ring cell cancer. Currently, there is information available from 96 total gastrectomies in the setting of HDGC,⁴⁴ approximately three-quarters of which were performed in asymptomatic *CDH1* carriers following negative screening endoscopy and biopsies. Only three cases did not show evidence for early invasive carcinoma, and in two of these, tiny foci of in situ signet ring cell carcinoma were observed.⁴⁴ Although malignant foci are generally localized to the proximal one-third of the stomach,⁶⁴ lesions may be distributed throughout the entire stomach, necessitating a total gastrectomy for comprehensive prevention. The optimal timing of prophylactic gastrectomy is unknown but is generally recommended when the unaffected carrier is 5 years younger than the youngest family member who has developed clinical symptoms of HDGC. Clinical management and screening strategies remain uncertain for families who meet criteria for HDGC but are negative for *CDH1* mutations or variants of unknown significance, although a screening endoscopy is often suggested.

The impact and long-term outcomes of prophylactic gastrectomy on carriers' lifestyle and health are significant, particularly because 20% to 30% of carriers may never develop invasive gastric cancer. Certainly, all patients experience some level of morbidity, including diarrhea, weight loss, and difficulty eating. Mortality due to this indication for a gastrectomy has not been reported. Early evidence suggests that women can successfully carry healthy pregnancies after a gastrectomy.⁶⁵ Most importantly, to date, there have been no reports of gastric cancer recurrence in a member of an HDGC family after a prophylactic total gastrectomy.

Women with HDGC also exhibit up to 60% lifetime risk for developing breast cancer, primarily of the lobular type, and as more women are prevented from developing diffuse gastric cancer, breast cancer screening is of great relevance. The correct approach to screening for lobular breast cancer in women with HDGC is not known, but is based on approaches used in other hereditary breast cancer susceptibility syndromes. Although prophylactic mastectomies have been shown to effectively prevent the development of breast cancer and result in improved long-term survival in *BRCA1/2* mutation carriers, such an approach remains completely investigational for women in HDGC families. The prognosis of lobular cancers that develop in HDGC patients is currently unknown, and given the relatively late onset compared with breast cancers in *BRCA1/2* carriers, prophylactic mastectomies may not be appropriate. Therefore, standard screening recommendations include annual breast magnetic resonance imaging (MRI) and mammogram starting at the age of 35 years.^{66,67} An open question is whether chemoprevention with tamoxifen may benefit women with HDGC, given its role in reducing breast cancer risk in half in women at elevated risk because of age, family history, or history of biopsy-proven lobular carcinoma in situ.⁶⁸

In summary, individuals from HDGC families with inherited germ-line mutations in the *CDH1* gene face up to an 80% likelihood of developing gastric cancer and, for women, an additional 60% chance of developing lobular breast cancer during their lifetime, with significant risk beginning at relatively young ages. Such levels of overall cancer risk are similar to that of developing breast or colon cancer for carriers of *BRCA1* or 2 gene mutations, or mismatch repair gene mutations, respectively. Therefore, rigorous surveillance and the consideration of prophylactic surgery are important for the management of these individuals. At the very least, a regular endoscopic examination with a random biopsy of the stomach should be performed every 6 to 12 months, probably starting 10 years earlier than the youngest affected patient in the

family, or by the age of 25 years. Because mucosal abnormalities tend to occur late in diffuse gastric cancer and delay the endoscopic diagnosis, a prophylactic gastrectomy should be seriously considered as a means of preventing gastric carcinoma, although it clearly comes with high morbidity. It is somewhat less clear as to the correct approach for the screening and prevention of lobular breast cancer in women with HDGC. Adherence to standard recommendations for screening mammographies for breast cancer should be followed. The consideration of investigative approaches to screening with MRI and chemoprevention with tamoxifen or other agents are appropriate. The decision to perform a prophylactic gastrectomy should be balanced with age-based risk, based on age-specific penetrance data, as well as many other personal factors. Therefore, it is essential that patients carrying the gene have the opportunity for extensive counseling, discussion, and reflection with knowledgeable clinicians, geneticists, and counselors before making the decision to proceed.

OTHER HEREDITARY CANCER SUSCEPTIBILITY SYNDROMES WITH INCREASED GASTRIC CANCER RISK

Lynch Syndrome

The seminal report of a family with dominantly inherited colon and gastrointestinal (GI) cancers in 1979 by Lynch and Lynch⁶⁹ began decades of defining and refining this hereditary syndrome. Lynch syndrome is caused by a germ-line mutation in a mismatch DNA repair gene (*MLH1*, *MSH2*, *MSH6*, *PMS2*, or *EPCAM*) and is thus associated with tumors exhibiting microsatellite instability (MSI). It is estimated that 2% to 4% of all diagnosed colorectal cancers⁷⁰ and 2% to 5% of all diagnosed endometrial cancers⁷¹ are due to Lynch syndrome. With a frequency estimated at 1 in 440 in the United States,⁷² it is similar to the *BRCA* carriage rate. The lifetime risks for Lynch syndrome-associated cancers are highest for colorectal cancer at 52% to 82% (mean age at diagnosis, 44 to 61 years), followed by an endometrial cancer risk of 25% to 60% in women (mean age at diagnosis, 48 to 62 years), a 6% to 13% risk for gastric cancer (mean age at diagnosis, 56 years), and 4% to 12% for ovarian cancer (mean age at diagnosis, 42.5 years).⁷⁰⁻⁷⁸

Lynch syndrome-associated gastric cancers predominantly show intestinal histology (more than 90% of the cases). This correlation echoes the strong association between MSI tumor phenotype and intestinal gastric cancer. The International Collaborative Group on hereditary nonpolyposis colorectal cancer (HNPCC) developed the original Amsterdam Criteria in 1991. Revisions followed, with Bethesda criteria outlined in 1997 and revisions in 2004 with the inclusion of extracolonic tumor risks, including gastric cancer.^{79,80}

MSI screening by molecular and/or immunohistochemistry for the four common Lynch protein products (*MSH2*, *MSH6*, *MLH1*, and *PMS2*) should be considered in families who meet the Bethesda criteria. Because 15% of all gastric tumors exhibit MSI histology, the majority of these have acquired this mutator phenotype through sporadic mutations, and further germ-line testing of individuals with MSI-positive tumors is necessary to confirm a molecular diagnosis of Lynch syndrome.

Hereditary Breast Ovarian Cancer Syndrome

Hereditary breast and ovarian cancer due to germ-line *BRCA1* and *BRCA2* mutations is perhaps the most well-defined and recognized inherited cancer syndrome. With a prevalence of 1 in 300 to 400 in most populations and up to 1 in 40 in selected groups with founder mutations (most notably those with Ashkenazi Jewish ancestry), it represents the most common of the hereditary disorders

due to high-risk mutations. Carriers face a five- to six-fold increased risk of generally early-onset breast cancer and 10- to 20-fold increased risk for ovarian, fallopian, and primary peritoneal malignancies. Male carriers have a recognized increased risk for prostate cancer and male breast cancer. *BRCA1* and *BRCA2* have been implicated in multiple cellular functions but serve primary roles as tumor suppressor genes recruited to maintain genomic stability through DNA double-strand break repair. Following the cloning of the *BRCA1* and *BRCA2* genes in 1994 and 1995,^{81,82} the Breast Cancer Linkage Consortium convened to pool data and generate a body of clinical information to assist in the counseling and management of *BRCA* carriers, resulting in a seminal publication outlining the spectrum of *BRCA* mutation-associated cancer risks. In 173 breast-ovarian cancer families with *BRCA2* mutations from 20 centers in Europe and North America, the RR of gastric cancer was 2.59 (95% confidence interval [CI], 1.46 to 4.61).⁸³ Carriers of the 6174 delT *BRCA2* Ashkenazi Jewish founder mutation in Israel found gastric cancer to be the most common malignancy after breast and ovarian. Conversely, 5.7% of patients with gastric cancer in Israel were found to carry this *BRCA2* mutation⁸⁴; 20.7% of a Polish cohort of families with both gastric and breast malignancies were attributable to mutations in *BRCA2*. A *BRCA2* mutation was also found in 23.5% of women with ovarian cancer and a family history of stomach cancer in this population.^{85,86}

Several studies have implicated *BRCA1* mutations as a risk factor for gastric cancer. A large Swedish population-based study published in 1999 involving 150 malignant tumors from 1,145 relatives in *BRCA1* found an RR of 5.86 (95% CI, 1.60 to 15.01) and observed that gastric cancer diagnosed before the age of 70 years was twice as common in carrier families compared with the general population. They did not observe the same risk with *BRCA2*.^{87,88}

Brose et al.⁸⁹ observed the highest RR for gastric cancer (6.9) in 147 families with *BRCA1* mutations in Pennsylvania. Risch et al.⁹⁰ also observed an RR of 6.2 in first-degree relatives of 39 *BRCA1* mutation carrier families and, to a lesser extent, in 21 *BRCA2* families in Ontario, Canada.

More recently, a meta-analysis of more than 30 studies of tumor risk in *BRCA1* and *BRCA2* carriers found an RR of 1.69 (95% CI, 1.21 to 2.38) for gastric cancer, the highest risk after breast, ovarian, and prostate, followed closely by pancreatic cancer, with an RR of 1.62 (1.31 to 2.00).⁹¹ No pathology details were included in these studies, and it is unknown if one of the histologic subtypes of gastric cancer predominates in *BRCA*-associated tumors.

Familial Adenomatous Polyposis

FAP is a rare colon cancer syndrome associated with the striking presentation of early-onset multiple colonic adenomas and, in classic form, a near-complete certainty of early colon cancer without prophylactic surgical intervention. Incidence estimates for FAP range from 1 in 10,000 to 20,000, and almost one-third of those diagnosed carry a *de novo* mutation, making family history unreliable for ascertainment of many cases. Extracolonic findings include upper GI adenomas, fundic gland polyps, and desmoids tumors. A wide spectrum of extracolonic tumors can occur, including relatively rare cancers such as hepatoblastomas, duodenal adenocarcinomas, and adrenal, pancreatic, thyroid, biliary tract, and brain tumors. Additional diagnostic aids can include the finding of congenital hypertrophy of the retinal pigment epithelium, supernumerary teeth, osteomas, cutaneous lipomas, and cysts.

It is estimated that the lifetime risk for upper GI cancer in FAP is approximately 4% to 12%, of which only 0.5% to 2% are gastric cancers, although this risk has been reported as 7- to 10-fold higher in Asia.^{75,92,93} Approximately 50% of individuals with FAP have gastric fundus polyps, and 10% have adenomas of the stomach. Although gastric fundus polyps are unlikely to have malignancy potential, gastric adenomas can occasionally develop into invasive

disease.⁹⁴ Prophylactic gastrectomies are even discussed for diffuse fundic gland polyps showing high-grade dysplasia or large polyps.⁹⁵ Attenuated FAP is a muted form of classic FAP characterized by fewer than 100 colonic adenoma, a later median age and lower overall risk of colon cancer, and a high proportion of fundic gland polyps, suggesting a measurable risk for gastric cancer.⁹⁶⁻⁹⁹

Li-Fraumeni Syndrome

LFS is a devastating cancer syndrome with an extremely high risk for a multitude of tumor types. The most common malignancies are early-onset breast cancers and sarcomas, followed by brain tumors, leukemia, lung cancer, and then gastric cancer.¹⁰⁰ Four families were originally described by Drs. Li and Fraumeni¹⁰¹ in 1969. The risk of an initial primary cancer is 50% by the age of 30 years and 90% by the age of 70 years,¹⁰² with sex-specific differences in lifetime cancer risk of 73% in males and close to 100% in females primarily accounted for by an excessively high breast cancer risk.¹⁰³ There are high risks for multiple primary cancers, with 60% of carriers developing a second tumor and 4% developing a third malignancy.¹⁰⁴ Previously thought to be extraordinarily rare with an incidence of 1 in 50,000 to 100,000, recently relaxed testing criteria suggest the actual carrier rate may be several times higher. Of individuals who meet classic LFS clinical criteria, 70% are found to carry a *TP53* germ-line mutation. The *de novo* mutation rate is now estimated at 7% to 20%.¹⁰⁵ A negative family history can no longer exclude the consideration of LFS, and clinical criteria have been updated to recommend *P53* testing for single cases of adrenal cortical carcinoma, choroid plexus carcinoma, and breast cancer under the age of 30 years.

Although not one of the hallmark tumors of LFS, the International Agency for Research on Cancer database reports that gastric cancer is frequency seen in up to 2.8% of LFS families.¹⁰⁶ Somatic *TP53* alterations are associated with both the intestinal and diffuse forms of gastric cancer in equal frequency. However, *TP53* constitutional mutations are very rarely documented in the overall gastric cancer mutational spectrum. Among 62 *TP53* mutant LFS families seen at the Dana-Farber Cancer Institute in Boston and the National Cancer Institute, gastric cancer was diagnosed in 4.9% of affected members.¹⁰⁷ The mean and median ages at gastric cancer diagnosis were 43 and 36 years, respectively (range, 24 to 74 years), compared with the median age of 71 years in the general population based on Surveillance Epidemiology and End Results (SEER) data. Five families (8.1%) reported two or more cases of gastric cancer. A pathology review of the available tumors revealed both intestinal and diffuse histologies. A study of 180 families with LFS in the Netherlands found a concordant rate of gastric cancer among carriers with an RR of 2.6 (95% CI, 0.5 to 7.7).¹⁰⁸

Peutz-Jeghers Syndrome

Peutz-Jeghers syndrome (PJS) is a rare inherited disorder of GI hamartomas, polyposis, and, most strikingly, early development of pigmented lesions on the lips, oral mucosa, and fingers. Incidence rates are estimated in the range of 1 in 25,000 to 250,000. Initially described by Peutz¹⁰⁹ in 1921 and subsequently by Jeghers et al.¹¹⁰ in 1949, PJS is characterized by both hamartomatous and adenomatous polyposis throughout the GI tract and a high predisposition to GI malignancies. The clinical diagnosis of PJS is made on the basis of histologically confirmed hamartomatous polyps and two of the following: (1) positive family history, (2) hyperpigmentation of the digits and mucosa of the external genitalia, and (3) small bowel polyposis.¹¹¹ The mucocutaneous hyperpigmentation characteristically occurs on the buccal mucosa or near the eyes, nose, mouth, axilla, or fingertips. Typically noticeable by the age of 5 years, they frequently fade by puberty. Classic pigmented lesions in a first-degree relative of a diagnosed individual are sufficient to meet criteria for PJS.

TABLE 47.2

Inherited Cancer Syndromes with Associated Gastric Cancer Risks

Cancer Syndrome	Gene	Frequency	Gastric Cancer Risk (%)	Reference
HDGC	<i>CDH1</i>	Vary rare	>801	Fitzgerald et al. ⁴⁴
Hereditary breast/ovarian cancer	<i>BRCA1/2</i>	1/40–1/400	2.6–5.5	Brose et al. ⁸⁹
Lynch syndrome	<i>MLH1, MSH2, MSH6, PMS2, Epcam</i>	1/440	6–13	Chen et al., ⁷² Watson et al. ⁷⁷
Li–Fraumeni syndrome	<i>P53</i>	1/5,000	2.8	Gonzalez et al. ¹⁰⁵
FAP	<i>APC</i>	1/10–20,000	0.5–2.0	Garrean et al. ⁹²
Juvenile polyposis	<i>SMAD4, BMPR1A</i>	1/16–100,000	21	Howe et al. ¹²¹
PJS	<i>STK11</i>	1/25–250,000	29	Giardiello et al., ¹¹³ van Lier et al. ¹¹⁴

Chronic GI bleeds, anemia, and recurrent obstruction due to intussusception are frequent complications and often require surgical intervention. Among GI cancers, gastric cancer was found to be the third most frequent tumor in PJS, after small intestine and colorectal carcinoma. The cumulative cancer risk is 47% at the age of 65 years.¹¹² RRs reported for colon, stomach, and small intestine neoplasms have been as high as 84, 213, and over 500, respectively.¹¹³ Increased risk is also present for other GI cancers (e.g., pancreatic, esophageal), as well as neoplasms outside the GI tract (lung, breast, ovarian, and endometrial). Other tumors associated with PJS are benign ovarian tumors called sex cord tumors with annular tubules, calcifying Sertoli tumors of the testes, and adenoma malignum of the cervix.

A Dutch team reviewed 20 PJS cohort studies and 1 meta-analysis published between 1975 and 2007 with a total of 1,644 patients.^{114,115} They found the cumulative lifetime risks of GI cancers of 38% to 66%, and for all cancers, a lifetime risk range of 37% to 93%. Specifically, the gastric cancer risks were 29%, the third most common malignancy after colorectal and breast cancers. Understandably, this prompted a call for screening upper endoscopies every 2 to 5 years starting at the age of 20 years, whereas others suggested initiating endoscopies at the age of 8 years with addition of colonoscopies at the age of 20 years and breast screening at the age of 25 years.

STK11/LKB1 is the only gene identified to cause PJS, and mutations are found in 70% of those who meet clinical criteria.¹¹⁶ Of affected individuals, 50% have a family history of PJS, and 50% may represent de novo mutations, although the penetrance of PJS has yet to be confirmed. The absence of a mutation in *STK11* does not preclude a diagnosis of PJS in individuals meeting the clinical diagnostic criteria.

Juvenile Polyposis Syndrome

Juvenile polyposis syndrome (JPS) is another very rare, hereditary cancer syndrome with a broadly defined incidence rate between 1 in 16,000 and 1 in 100,000.^{117–120} The diagnosis is based on the presence of multiple hamartomatous polyps with a distinct morphology termed *juvenile*, although JPS is not restricted to development in childhood. Solitary juvenile polyps occur in 1% to 2% of the general population.

The diagnosis of JPS requires more than five juvenile polyps in the colorectum, multiple juvenile polyps throughout the GI tract, or a number of juvenile polyps in an individual with a known family history of juvenile polyps. There is wide interfamilial and intrafamilial variability in number and distribution of polyps. Juvenile polyps are commonly benign, but the risk of malignant transformation is present. Larger polyps have been noted to contain

adenomatous regions, resulting in a high lifetime risk of colorectal cancer approaching 20% by the age of 35 years and 68% by the age of 60 years. Gastric cancer has been found in 21% of JPS patients affected with gastric polyps, and increased incidence of pancreatic and small bowel cancers has also been reported (Table 47.2).⁽¹²¹⁾

Approximately 75% of JPS cases are familial, and 25% of JPS cases appear to be de novo. Two genes have been implicated as the cause of JPS in 40% of affected individuals: *SMAD4* (or *MADH4*) and *BMPR1A*, with an approximate equal frequency.^{121,122} The majority of JPS cases are due to as yet unidentified gene(s). Mutations in *SMAD4* are also associated with hereditary hemorrhagic telangiectasia (HHT), also known as Osler–Weber–Rendu syndrome. HHT is associated with visceral bleeding, telangiectasias, or arteriovenous malformations. Currently, 15% to 22% of *SMAD4* mutation carriers are suspected of having combined JPS/HHT.¹²³

Surveillance recommendations for screening individuals with JPS include monitoring for rectal bleeding, anemia, and GI symptoms from infancy and additional complete blood counts, upper endoscopies, and colonoscopies at the age of 15 years, or when symptoms are present. An endoscopy is repeated every 1 to 3 years, depending on polyp load. In families with *SMAD4* mutations, HHT surveillance begins in early childhood.

CONCLUSIONS

Hereditary gastric cancer is a relatively unusual disease. Given the very poor prognosis for most gastric cancer patients once diagnosed, every effort should be made to identify lesions early when they are still curable. Genetic testing for gastric cancer susceptibility allows for the identification of families with elevated risk for this and other tumors and the development of rational surveillance strategies for early detection. Unfortunately, reliable screening tools for gastric cancer are not available, and prophylactic surgical gastrectomies have proven beneficial in certain autosomal-dominant, high-penetrance genetic syndromes, including HDGC caused by germ-line *CDH1* mutations. Genetic testing for other gastric cancer risk genes may also be warranted, as reviewed here. Major goals for clinical cancer genetics include identifying additional risk alleles to explain cancer susceptibility in families without known germ-line variants and to develop more robust tools for clinical screening for gastric cancer in high-risk individuals. Finally, the advent of whole genome sequencing of germ-line DNA and tumor genomes will lead to the rapid identification of novel variants and risk alleles of various penetrance. A challenge for the next generation of cancer genetics professionals will be the interpretation of multiple rare variants found in personal genomes and integration with schemes for the prevention and early detection of gastric cancer.

48 Molecular Biology of Pancreas Cancer

Scott E. Kern and Ralph H. Hruban

INTRODUCTION

Pancreatic cancer is a genetic disease. This perspective is supported by reproducible patterns of genetic mutations that accumulate during pancreatic tumorigenesis. These patterns indicate the operation of a selective process favoring the emergence of specific constellations of genetic changes. According to this genetic theory, most pancreatic cancers share a common foundation of genetic mutations disrupting specific cellular regulatory controls. These shared abnormalities are responsible for the processes of cancer growth, invasion, and metastasis in individual patients.

Four categories of mutated genes play a role in the pancreatic tumorigenesis: oncogenes, tumor-suppressor genes, genome-maintenance genes, and tissue-maintenance genes (summarized in Table 48.1). Some of these mutations are germline (i.e., they are transmitted within a family), whereas somatic mutations, acquired during life, contribute to tumorigenesis within a tissue but are not passed to offspring.

The most common cancer type of pancreatic cancer is pancreatic ductal adenocarcinoma (PDA). PDA is the primary focus of clinical and molecular research and is thus highlighted in this chapter. Other clinically and molecularly distinct forms of cancer occur in the pancreas and must be distinguished from PDA; they are discussed here in lesser detail.

In recent years, techniques were developed to sequence all of the genes of individual cancers. Whole-exome sequencing of PDAs revealed an average of 63 somatic mutations per tumor.¹ Most of these mutations undoubtedly are nonfunctional *passenger* mutations, each mutated at a low frequency and not contributing to tumorigenesis. Indeed, most passenger mutations might arise as tissues age before tumorigenesis even begins.² Smoking is associated with a doubling of the risk for pancreatic cancer, and remarkably, it is also associated with a 40% increase of the prevalence of low-frequency mutations in the cancers.³ Only a subset of the mutations in PDA, however, are responsible for *driving* the neoplastic process in the ducts; only they are discussed further here. Modeling of a comprehensive study mapping gene mutations in multiple regions of primary PDAs and their metastases indicated a general timeline of tumorigenesis, invasion, and metastasis. According to this model, about a decade of time passes between the first driver mutation initiating the precursor neoplasm and the emergence of the first cell having the genotype of the invasive cancer; metastatic ability is acquired after another 5 years, and with patient death following about 2 years later.⁴

Telomere abnormalities and manifestations of chromosome instability are the most common alterations in pancreatic neoplasia. Four genes are mutated in most PDAs: the *KRAS*, *p16/CDKN2A*, *TP53*, and *SMAD4/DPC4* genes. Other recurrent genetic abnormalities are seen at a lower frequency, including internal deletions of exons of *FAM190A/CCSER1*; mutations in the genes *BRCA2*, *PALB2*, *FANCC*, *FANCG*, *FBXW7*, *BAX*, and *RB1*, in the transforming growth factor beta (TGF- β) receptors *TGFBR1* and *TGFBR2*, in the activin receptors *ACVR1B* and *ACVR2*, in various chromatin-remodeling genes such as *ARID1A*, in the genes *MKK4*, *STK11*,

MLL3, *ATM*, *GUCY2F*, *NTRK3*, and *EGFR*, and in cationic tryptophan; alterations in the mitochondrial genome; amplifications; various chromosomal deletions; inactivation of DNA mismatch-repair genes; and rarely, the maintenance of the Epstein-Barr virus genome as an episome. Irregular sizes and numbers of centrosomes were observed in 85% of pancreatic cancers and some adenomas, but in no tissues of chronic pancreatitis or normal pancreas.⁵

Knowing the genes that are mutated in a cancer can have direct clinical impact. For example, some patients develop pancreatic cancer because of an inherited mutation, and these patients and their families could benefit from genetic counseling.⁶⁻⁹ A distinct morphologic subtype of pancreatic cancer, the medullary cancer, can suggest such an inherited mutation.^{10,11} Another example of clinical impact includes the analysis of the genetic alterations in precursors to invasive pancreatic neoplasia, which indicated that most carcinomas arise by a process of progressive intraductal tumorigenesis, suggesting that these intraductal lesions might be detected and treated before a patient develops an invasive cancer.¹² Epigenetic changes in DNA methylation and in gene expression are also highly specific for the cancerous cells and can serve as markers of disease.

COMMON MOLECULAR CHANGES

Telomere shortening is an early and prevalent genetic change identified in the pancreatic precursor lesions.¹³ Telomere shortening experimentally predisposes cells to chromosome fusion (translocations) and the missegregation of genetic material during mitosis.¹⁴ Later in tumorigenesis, the telomerase is often reactivated,^{15,16} moderating the telomere erosive process while permitting continued chromosomal instability.¹⁷

The *KRAS* gene mediates signals from growth factor receptors and other signaling inputs (Fig. 48.1). The mutations present in most pancreatic cancers convert the normal *Kras* protein (a protooncogene) to an oncogene, causing the protein to become overactive in transmitting growth factor-initiated signals.¹⁸ *KRAS* is mutated in over 90% of conventional pancreatic ductal carcinomas.¹⁹ Among the first genetic changes in the ducts is a *KRAS* gene mutation (see Table 48.1),^{20,21} and recent evidence from advanced gene sequencing techniques indicates that their prevalence in early lesions is higher than was previously thought.²²

As one of the most commonly mutated genes in pancreatic cancer, the Ras protein is an attractive target for the development of gene-specific therapies, and an understanding of the normal biology of the Ras protein should help in the development of these Ras-targeted therapies. Ras proteins require an attachment to the plasma membrane for activity. For many proteins, including Ras, a hydrophobic prenyl group is essential for the attachment. Either farnesyl (15-carbon) or geranylgeranyl (20-carbon) makes a covalent thioether linkage at a cysteine residue located near the C-terminal end of Ras proteins, termed the CAAX motif. Working mostly in artificial legacy models of the *HRAS* oncogene (rather than the more widely available but experimentally less tractable natural *KRAS*-mutant cancer cell lines), the farnesylation reaction

^a Stage of appearance of the genetic changes during the intraductal precursor phase of the neoplasm, where known. For *BRCA2*, most mutations are inherited, but the loss of the second allele is reported only in a single advanced pancreatic intraepithelial neoplasia.

^b Few homozygous deletions of the *TGFBR1* gene and the *TGFBR2* gene have been identified in non-MSI (microsatellite instability) pancreatic cancers.

^c The prevalence of exonic transcript deletions is much higher than the prevalence of homozygously deleted exons given here.

^d In MSI+ tumors, the mismatch repair defect is usually somatic in origin; the *TGFBR2*, *ACVR2*, and *BAX* alterations are somatic.

^e A single example of homozygous mutation of the *FBXW7* gene is reported in a series having a 6% prevalence of cyclin E overexpression. To date, cyclin E amplification is reported only in cell lines.

^f The prevalence of mutations in severely affected families is higher than the prevalence among unselected cancers given here.

Som., (prevalence of) somatic mutation or methylation; Germ., (prevalence of) germline mutation.

was readily inhibited by various means; in these models, the Ras protein was rendered inactive and was often accompanied by cytotoxicity limited to the mutant cells.

Although many types of compounds capable of blocking the farnesyltransferase enzyme were developed as drugs, they have not been successful anticancer agents. Reasons are many. Although the Hras protein is linked predominantly through farnesyl groups, the Kras protein can be alternately prenylated by geranylgeranyl linkages. The latter is thought to be critical for a wider number of cellular proteins, and for fear of excessive toxicity, geranylgeranyl linkages have not usually been considered as an attractive drug target. The Kras protein may bind more tightly than Hras to the farnesyltransferase enzyme, necessitating higher drug concentrations.¹⁸

Additionally, the artificial models usually employed the engineered overexpression of the Ras protein, a situation in which the unattached Ras proteins would serve as a dominant-negative inhibitor, binding the essential interacting proteins and sequestering them in the cytoplasm to ensure the inactivation of the many downstream Ras pathways. Such a concentration-driven mechanism would presumably not occur under the normal levels of Ras proteins present in human cancers.²³ Indeed, it is proposed that the limited efficacy of farnesyltransferase inhibitors (FTI) observed in some experimental models and in clinical trials may be attributable to a cellular target not yet identified.²⁴ Attention has turned to compounds that target the downstream mediators, such as Raf and Mek protein kinase inhibitors.

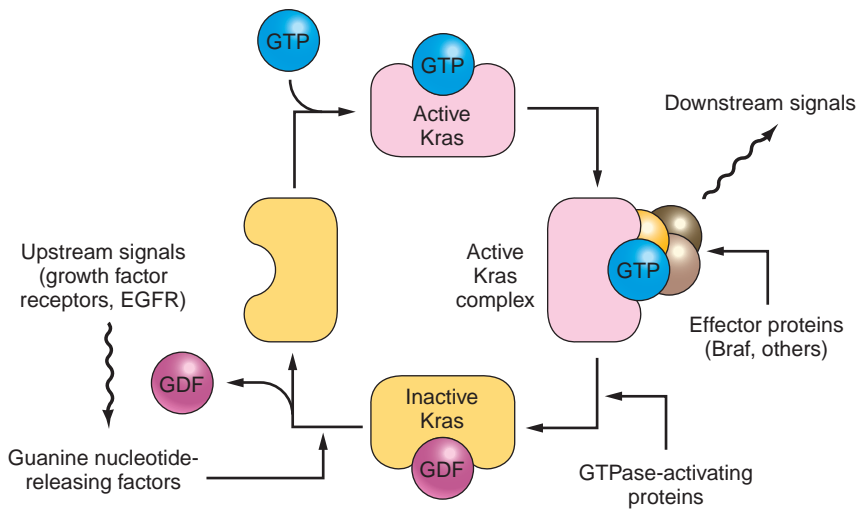

Figure 48.1 The KRAS pathway. KRAS normally integrates and regulates signals arising in the growth factor receptors that are passed to KRAS using the Grb2 and the Sos1 nucleotide exchange factor. The active GTP-bound form of KRAS recruits effector proteins such as Raf1 and Braf, in turn stimulating the downstream mitogen-activated protein kinases, such as MEK and ERK, and activating certain transcription factors. The EGF receptor can be overexpressed and occasionally mutated to provide inappropriately strong upstream signals, and the BRAF protein can be activated by point mutation, but more often in pancreatic cancer, the Kras protein is mutated. These latter mutations impair the GTPase-activating protein (GAP)-stimulated reaction that normally returns KRAS to the inactive state.

The Smad pathway mediates signals initiated upon the binding of the extracellular proteins TGF- β , activin, and bone morphogenic proteins to their receptors (Fig. 48.2). These signals are transmitted to the nucleus by proteins of the Smad family of related genes, including *SMAD4* (*DPC4*).²⁵ Once in the nucleus, Smad protein complexes bind specific recognition sites on DNA and cause the transcription of certain genes.²⁶ Mutations in the *SMAD4* gene are found in nearly half of pancreatic carcinomas, including homozygous deletions or intragenic mutations combined with loss of heterozygosity (LOH).²⁷ Other Smad genes are also occasionally mutated in pancreatic cancer.¹ Also, homozygous deletions and mutation/LOH affecting the TGF- β receptor genes are seen in a few pancreatic cancers.²⁸ A more common abnormality, in pancreatic as well as in other tumor types, is the underexpression of TGF- β receptors, which may render cells resistant to the normal suppressive effects of the TGF- β ligand.²⁹

The *p16/RB1* pathway is a key control of the cell division cycle (Fig. 48.3). The retinoblastoma protein (Rb1) is a transcriptional regulator and regulates the entry of cells into S phase. A complex of cyclin D and a cyclin-dependent kinase (Cdk4 and Cdk6) phosphorylates and thereby regulates Rb1. The p16 protein is a Cdk-inhibitor that binds Cdk4 and Cdk6.^{30–32} Virtually all pancreatic carcinomas suffer a loss of *p16* gene function through homozygous deletions, a mutation combined with LOH, or promoter

methylation of the *p16/CDKN2A* gene associated with a lack of gene expression.^{33,34} In addition, inherited mutations of the *p16/CDKN2A* gene cause a familial melanoma/pancreatic cancer syndrome known as familial atypical multiple mole melanoma (FAMMM).^{35–39} Only rare pancreatic cancers have an inactivating mutation of the *RBI* gene.⁴⁰

The protein product of the *TP53* gene, Tp53, binds to specific sites of DNA and activates the transcription of certain genes that control the cell division cycle and apoptosis.^{41,42} The Tp53 protein, normally a short-lived protein, becomes phosphorylated and stabilized after DNA damage and other cellular stresses (Fig. 48.4). In about 75% of pancreatic cancers, the *TP53* gene has point mutations that inhibit the ability of p53 to bind DNA or, occasionally, other types of inactivating mutation.^{43–45}

Most human carcinomas have chromosomal instability (CIN), which produces changes in chromosomal copy numbers or aneuploidy.⁴⁶ Most pancreatic cancers have complex karyotypes, including deletions of whole chromosomes and subchromosomal regions.^{47–49} CIN is the process that causes most of the tumor deletions (i.e., LOH).⁵⁰ A few percent of pancreatic carcinomas, however, do not have significant gross or numerical chromosomal changes and instead have a different form of genetic instability; they have defects in DNA mismatch repair, producing high mutation rates at sites of simple repetitive sequences (microsatellites), termed microsatellite instability (MSI).^{10,11,51–54} The pattern of

Figure 48.2 The TGF- β /Activin/Smad pathway. Dimeric kinase receptors of the TGF- β superfamily respond to extracellular ligands, causing phosphorylation of one or more of the receptor-associated Smad proteins and leading them to complex with the unphosphorylated common Smad, Smad4. This complex binds to specific DNA sequences and works with other transcription factors to stimulate gene expression. Mutations in pancreatic cancer can inactivate either partner of the dimeric receptors that respond to extracellular TGF- β or activin. More commonly, however, mutations and large deletions in the *SMAD4* gene destabilize its protein product or ablate gene expression.

Figure 48.3 The p16/Rb1 pathway. p16 binds to, inhibits, and thereby controls the availability of the cyclin-dependent kinases Cdk4 and Cdk6 (not shown). When activated by binding to cyclin D, these kinases phosphorylate and thereby inactivate the Rb1 tumor-suppressor protein. The activity of p16 is controlled in a complex manner, through changes in gene expression and by displacement reactions involving other similar kinase inhibitor proteins. p16 mutations and deletions are nearly ubiquitous in pancreatic cancer, resulting in dysregulation of these cyclin-dependent kinases that regulate the cell division cycle.

genetic damage in these carcinomas differs considerably from the pattern in carcinomas with CIN. The type II TGF- β and activin receptors (*TGFBR2*) and (*ACVR2*), as well as the *BAX* gene, have a repetitive sequence within their protein-coding regions, and biallelic inactivating mutations of these sequences are seen in many MSI pancreatic cancers.^{28,54-57}

There are also alterations in pancreatic carcinomas, some probably being important to tumorigenesis, that are not attributed to genetic mutations. These include the expression of telomerase,^{15,16} the underexpression of TGF- β receptors,²⁹ and the overexpression of the growth-stimulating Her-2/neu cell surface receptor⁵⁸⁻⁶¹ and growth factor-related proteins.⁶² Some of these activities are proposed to be attractive as therapeutic targets, although supportive clinical evidence is not yet available. Pancreatic carcinomas also have reproducible alterations in gene expression, such as overexpression of the proteins mesothelin and prostate stem cell antigen (PSCA), that currently can serve as diagnostic aids in the histopathologic interpretation of biopsies and surgical resections.⁵⁷⁻⁵⁹

The epigenetic patterns of gene hypermethylation and various patterns of overexpression of RNA transcripts and proteins in pancreatic cancers are considered promising for developing additional diagnostic markers for the analysis of pancreatic secretions and for noninvasive diagnostic screening.⁶⁵

Genetic patterns are also found among other diagnostic categories of pancreatic neoplasia. The precursor lesions of PDAs, termed pancreatic intraepithelial neoplasia (PanIN), in their most advanced grade closely resemble the genetic patterns of the conventional invasive PDAs. However, the lesions other than the PDAs, including the intraductal papillary mucinous neoplasms (IPMN), the mucinous cystic neoplasms (MCNs), acinar cell carcinomas, well-differentiated neuroendocrine tumors, pancreatoblastomas, and solid pseudo-papillary neoplasms (SPNs), diverge significantly from the patterns of PanINs and typical invasive PDAs. These differences could be used in the future for differential diagnosis of lesions upon biopsy.

Cystic neoplasms such as IPMNs, serous cystadenomas (SCAs), MCNs, and SPNs appear to have relatively few mutant genes in

Figure 48.4 The p53 pathway. Many modes of control affect p53 activity, one of which is shown in the diagram. Stresses such as DNA damage result in the phosphorylation of p53, preventing its degradation by an Mdm2-directed pathway. When stabilized, p53 binds to specific DNA sequences and activates the transcription of many genes, including Mdm2 as part of a negative feedback loop. When p53 is mutated, it fails to bind effectively to DNA to activate transcription. Because Mdm2 then lacks its transcriptional stimulus from p53, mutant but inactive p53 proteins are usually expressed at very high levels.

each tumor, yet the genes involved are remarkably distinct.^{64–66} Mutations in *GNAS* or *KRAS* were found in 96% of IPMNs; those in *RNF43* were present in many IPMNs and MCNs; those in *CTNNB1* were ubiquitous among the SPNs; and those in *VHL* affected half of the SCAs. *GNAS* mutations were found in collected pancreatic secretions samples of two thirds of familial and sporadic cases of IPMNs, but not in controls, and their presence predicted subsequent emergence or increasing size of detected cysts.⁶⁷ *PIK3CA* mutations are present in some IPMNs and the colloid carcinomas that can derive from them.⁶⁸ *CTNNB1* (beta-catenin) mutations are present in virtually all solid-pseudopapillary neoplasms⁶⁹ and pancreatoblastomas.⁷⁰ These genetic data suggested utilities in detection, diagnostic classification, and prognostication when clinically managing pancreatic cysts.

Mutations of *MEN1* and either the *DAXX* or *ATRX* genes are found in most well-differentiated pancreatic neuroendocrine tumors (PanNET).^{71,72} Nearly two thirds of these tumors (a subset uniformly harboring *DAXX* or *ATRX* mutations) were found to have abnormal telomeres, indicating an active process termed alternative lengthening of telomeres (ALT). ALT is distinct from the typical activation of telomerase implicated in most types of cancer.⁷³ The distinguishing patterns of mutations also firmly establish that high-grade small- and large-cell neuroendocrine carcinomas of the pancreas, despite having histologic similarities with well-differentiated PanNETs, arise through different tumorigenic mechanisms.⁷⁴

Lower-Frequency Genetic Changes

The causative genes of *Fanconi anemia* play a role in human tumorigenesis. The *BRCA2* gene represents Fanconi complementation group D1 and is thought to aid DNA strand repair.⁷⁵ Because of this function, it is perhaps best to categorize *BRCA2* as a genome-maintenance gene rather than a conventional tumor-suppressor. As many as 7% of apparently *sporadic* pancreatic cancers (more, in instances of familial aggregation) harbor an inactivating intragenic inherited mutation of one copy of the *BRCA2* gene, accompanied by LOH.^{1,2,66} The *PALB2* gene represents Fanconi group N, and its protein product functions by binding the *Bra2* protein.⁷⁶ Three percent of familial pancreatic cancers harbored a germ-line inactivating mutation of *PALB2*, and in a tumor studied in depth, the other copy was inactivated by a somatic mutation.^{1,77,78} The *FANCC* and *FANCG* genes have somatic or germ-line mutations in some pancreatic cancer patients, again with loss of the wild-type allele in the cancer.⁷⁹ The known hypersensitivity of Fanconi cells to interstrand DNA cross-linking agents, such as cisplatin, melphalan, and mitomycin C, suggested that pancreatic cancers with Fanconi pathway genetic defects would be especially susceptible to treatment with such agents.^{80–83} Occasional complete remissions of pancreatic cancer have been reported with therapies that included DNA cross-linkers,^{84–88} and there are recent reports of prolonged responses using such agents in patients having *BRCA2* mutations.^{89,90} Cells made experimentally deficient for Fanconi genes are also hypersensitive to certain nongenotoxic compounds,⁹¹ and patients that have *BRCA2*-mutant cancers other than pancreatic cancer are reported to respond to therapeutic drug inhibition of the poly (ADP-ribose) polymerase enzyme, which normally becomes activated to facilitate DNA-strand repair.⁹² These opportunities are being explored in clinical trials.

A genomic mutational pattern (a *signature*) typical of cancers having *BRCA1* or *BRCA2* inactivation is reported in about 12% of pancreatic cancers.⁹³ This pattern involves nucleotide substitutions of broad diversity and indicates that the functions of *BRCA* genes extend to repair mechanisms not yet well explored. Among natural compounds tested, *BRCA2*- and *PALB2*-null cancers seem most hypersensitive to the toxicity of acetaldehyde,⁹⁴ a requisite metabolite of alcohol and a natural food constituent. Acetaldehyde

creates deoxynucleotide adducts, but the mutagenic effects of acetaldehyde in carriers of *BRCA2* and *PALB2* mutations are not yet explored with focused epidemiologic studies. Remarkably, *BRCA1* gene mutations were not found in unselected pancreatic cancers or pancreatic cancer families.⁹⁵ Nonetheless, pancreatic cancers do occur in carriers of *BRCA1*-inactivating mutations.^{96,97} In these persons, the relatively high rate of LOH affecting the other *BRCA1* copy indicates that a loss of *BRCA1* function likely fosters tumorigenesis in these patients.⁹⁶

A hotspot of genomic homozygous deletions affects the *FAM190A* gene, producing deletions of internal exons and typically resulting in in-frame deletions of the protein-coding sequence.^{98,99} In addition to these genomic mutations, more than a third of PDAs have similar in-frame deletions affecting the *FAM190A* transcripts and/or defective expression of the *Fam190a* protein, but yet without an identifiable genomic mutation.^{99,100} *Fam190a* functions in mitosis and in ensuring mononuclear daughter cells after the abscission (separation) phase of cell division.¹⁰⁰ *Fam190a* abnormalities thus might contribute to chromosomal instability during tumorigenesis.

The *mitochondrial genome* is mutated in a majority of pancreatic cancers.^{101–103} These mutations most likely represent genetic drift, and perhaps do not directly contribute to the process of tumorigenesis.¹⁰⁵ Such mutations, however, could potentially serve as a diagnostic target due to the large number of copies of the mitochondrial genome in human carcinoma cells.^{102,103}

Genes encoding components of the SWI/SNF chromatin-remodeling complex, including *ARID1A*, *ARID1B*, and *PBRM1*, are each occasionally mutated in PDA, in total affecting nearly a third of these tumors.^{104,105}

The *MAP2K4* (*MKK4*) gene participates in a stress-activated protein kinase pathway.^{81,82} It is stimulated by various influences, including chemotherapy, and its downstream effects include apoptosis and cellular differentiation. The *MKK4* gene is inactivated by homozygous deletions or mutation coupled with LOH in about 4% of pancreatic cancers.^{106,107} The experimental loss of one or both copies of the *MKK4* gene in cancer cells reduced Jun kinase activation and its expression. Such gene dose-dependent effects could rationalize the high rate of loss of chromosomal arm 17p, affecting 90% of pancreatic cancers and more than half of the *TP53* wild-type cancers.¹⁰⁸

Germ-line mutations of the *STK11* (*LKB1*) gene, a serine-threonine kinase, are responsible for Peutz-Jeghers syndrome (PJS).^{109,110} PJS was anecdotally associated with pancreatic cancer.¹¹¹ A follow-up study examined lifetime risk, finding nearly a third of PJS patients to have developed pancreatic cancer.¹¹² Sporadic pancreatic cancers, independent of PJS, also can lose the gene by homozygous deletion or by somatic mutation/LOH in about 4% of cases.¹¹³

Kinase oncogenes are mutated at low frequency, including the *GUCY2F*, *EGFR*, and *NTRK3* genes.^{91,92} This class of mutations is important in that these mutations can be targeted with anti-kinase drugs.⁹³

Gene amplification also occurs in pancreatic cancer. Amplified regions include the *AKT2* gene within an amplicon on chromosome 19q, which involves about 10% to 20% of cases studied.^{94–96} About 6% of pancreatic cancers overexpress the oncogene *CCNE1* (cyclin E). Two mechanisms have been demonstrated, cyclin E gene amplification and the genetic inactivation of the *FBXW7* (*AGO*) gene, which normally serves to degrade cyclin E during the normal phases of the cell division cycle.^{1,114}

The patterns of *chromosomal deletion* in pancreatic cancer are complex. In one study, from 1.5% to 32% of all tested loci in the PDAs of different patients had a deletion.¹¹⁵ For most lost regions, we know of no particular tumor-suppressor genes targeted by the deletions. Conversely, in some regions known to harbor tumor-suppressor genes, the known mutated genes do not justify the high observed prevalence rates of LOH unless gene dose-dependent effects are postulated.¹⁰⁸ Individual homozygous deletions are

found at some additional genetic locations, again without a definitive target gene yet identified for most of these events.⁹⁸

Defects in DNA mismatch repair (microsatellite instability, MSI) are seen in a small minority of pancreatic cancers. These cancers typically have a medullary histologic phenotype¹⁰ and mutations of the type II TGF- β (*TGFBR2*) and activin (*ACVR2*) receptor genes.^{28,55,56} They can also have mutations of the proapoptotic *BAX* gene⁵⁴ and of the growth factor pathway mediator *BRAF* gene (affecting the same pathway, presumably, as mutations of the *KRAS* gene).^{10,11,54,114} The MSI tumors do not have the propensity for large chromosomal alterations and gross aneuploidy.^{17,116} In a study of four cases of pancreatic cancers having MSI, all lacked expression of the Mlh1 protein.¹¹ Not all cancers with a medullary phenotype have MSI. Yet, medullary pancreatic carcinomas as a whole have a number of clinical and genetic differences as compared to those with conventional histologic appearance; the carcinomas have pushing rather than infiltrative borders, the *KRAS* gene often is wild type, and there is often a family history of malignancy.^{5,6,47} A reported case of Epstein-Barr virus (EBV)-associated pancreatic cancer¹¹ had a medullary phenotype with heavy lymphocytic infiltration. Due to its distinctive

features, it is advisable to separately designate the medullary category in the reporting of all clinical, genetic, and pathologic studies of pancreatic cancer.

Inherited or somatic inactivating mutations in the *ATM* gene accompany the loss of the wild-type allele of the cancers, indicating another tumor-suppressor gene for PDAs.^{117,118}

Inherited mutations of the cationic trypsinogen (*PRSS1*) gene prevent the inactivation of prematurely activated trypsin within the ducts, causing a familial form of severe, early-onset acute pancreatitis.¹¹⁹ Some affected kindred have a cumulative risk of pancreatic cancer that approaches 40% by the time the affected individuals reach 60 years of age.¹²⁰ This cancer diathesis falls in a unique category of cancer susceptibility, in that the predisposition emanates from genetic alterations of a tissue-maintenance gene, one that is not an oncogene, a tumor-suppressor gene, or a genome-maintenance gene.

In summary, pancreatic cancer is fundamentally a genetic disease. An understanding of the genes altered in pancreatic cancer has led to a better understanding of the familial aggregation of pancreatic cancer, which in turn, it is hoped, will lead to effective gene-specific targeted therapies for this deadly form of cancer.

INTRODUCTION

Pancreatic ductal adenocarcinoma (PDA) is the 12th most common cancer in the United States, but the 4th most frequent cause of cancer-related death.¹ There are 44,000 new cases of PDA each year in the United States and 38,000 deaths.² Although the death rates of most common cancers have declined over the past 80 years, the death rates for PDA have remained flat to slightly increased.¹ Based on demographic, incidence, and survival projections, PDA death rates are expected to eclipse death rates from breast and colon cancer within the next decade, and become the 2nd most deadly cancer. In short, PDA remains a deadly disease and is currently only curable in a minority of patients with localized and resectable disease.

Disease-specific survival has not changed significantly in the past 4 decades, regardless of disease stage. Patients with metastatic disease continue to have a 5-year survival of 2% or less.^{1,3,4} A recent single-institution, retrospective analysis of patients with resected PDA revealed similar overall survivals in the 2000s and the 1980s.⁵ The similarity in overall survival over time is not at all surprising considering the relatively modest advances in chemotherapy during this time. Although targeted and immunotherapies are now routinely used to treat certain other cancer types, personalized medicines with novel biologic therapies have not yet been successful for PDA.

This chapter provides a comprehensive overview of the pathobiology and management of pancreatic cancer, focusing on PDA. The less common types of pancreatic cancer (e.g., pancreatic neuroendocrine tumors and pancreatic cysts) will be discussed briefly. Current management strategies are placed in an historical context, and the latest understanding of the genetics and molecular biology of pancreatic cancer is reviewed. The management of PDA requires a multidisciplinary approach that involves surgeons, medical oncologists, radiation oncologists, radiologists, gastroenterologists, palliative medicine specialists, nurses, nutritionists, and many others. Herein, the roles of surgery, chemotherapy, and radiation will be emphasized. As much as possible, treatment strategies are framed in the context of the American Joint Committee on Cancer (AJCC) 7th edition staging scheme.⁶

STAGING

Pancreatic cancer is staged according to the AJCC, 7th edition, TNM staging system (Table 49.1).⁶ Presented survival data are based on 1998 data.⁷ T-stage is defined as follows: Tis is carcinoma in situ (pancreatic intraepithelial neoplasia [PanIN-3]); T1 is 2 cm or less and confined to the pancreas; T2 is greater than 2 cm and confined to the pancreas; T3 extends beyond the pancreas; and T4 invades visceral vessels, rendering the tumor unresectable. N-stage is defined as follows: N0 reflects no regional lymph node metastases; and N1 reflects regional lymph node metastases. M-stage is defined as follows: M0 reflects no distant metastases; and M1 reflects distant metastases.

EPIDEMIOLOGY

Like most cancers, PDA develops as a result of acquired genetic defects over many years, and therefore, most often occurs in the elderly. The median age at onset is 71 years, and nearly 74% of patients are diagnosed between the ages of 55 and 84. Only 12% of patients are diagnosed under 55, and 14% after the age of 84. The age-adjusted incidence rate in the United States is 12 out of 100,000, and the lifetime risk of developing PDA is 1.5%, or 1 in 67. African Americans have a slightly increased risk compared to Caucasians.⁸

Genetic Risk Factors

The greatest risk factor for pancreatic cancer is a strong family history. Approximately 10% of all pancreatic cancers are familial, defined as a family history involving at least two affected first-degree relatives (FDR) (e.g., parents, offspring, and siblings).⁹ The lifetime risk is 40% (32-fold) for patients with three or more affected FDRs, 10% for patients with two FDRs (6.4-fold), and 6% for patients with 1 FDR (4.6-fold).¹⁰ Some of the genetic defects underlying familial pancreatic cancer have been discovered, but known genetic defects only account for 10% to 15% of all familial cases.¹¹ Specific genetic abnormalities are discussed in greater detail in the Pathology and Biology section.

Environmental Risk Factors: Tobacco, Occupational Hazards, and Alcohol Consumption

Many environmental risk factors have been formally evaluated via meta-analyses performed by the Pancreatic Cancer Case Control Consortium (PanC4, <http://panc4.org/index.html>). Smoking tobacco is the best characterized environmental risk factor for PDA. A large meta-analysis of 83 studies calculated a relative risk increase at 1.74 for active smokers (this is substantially less than having even a single FDR).¹² Importantly, the risk decreases for former smokers, and returns to baseline after 20 years of smoking cessation.¹² These results were confirmed by the PanC4 consortium, which also noted that the number of daily cigarettes is directly proportional to the risk of developing PDA.¹³ Not surprising, high-risk individuals with a family history who also smoke carry twice the risk, compared to similar patients who do not smoke.^{14,15} Cigars are also associated with an increased risk for PDA, whereas smokeless tobacco is not.¹⁶ The impact of environmental tobacco smoke (i.e., second-hand smoke) on long-term risk is unclear.^{17,18} Among the many carcinogens in tobacco products, N-nitrosamines and the polycyclic aromatic hydrocarbons (PAH) are suspected to be the greatest culprits.¹⁹

With regard to occupational risk hazards, chlorinated hydrocarbons and PAHs have been most consistently found to correlate with PDA, and to increase relative risk by a comparable degree

TABLE 49.1

American Joint Committee on Cancer Staging for Pancreatic Cancer

Stage	T	N	M	Median Survival, All Patients (Months)	Median Survival, Resected Patients (Months)
0	Tis	N0	M0	N/A	N/A
1A	T1	N0	M0	10.0	24.1
1B	T2	N0	M0	9.1	20.6
IIA	T3	N0	M0	8.1	15.4

as smoking.²⁰ The former compound type is associated with dry cleaning and metal work, and, with the latter, exposure occurs with metalwork and aluminum production. According to the PanC4 consortium, mild or moderate alcohol consumption does not predispose one to PDA, whereas heavy alcohol consumption (≥ 9 drinks per day) is associated with an odds ratio (OR) of 1.6.²¹

Medical Risk Factors: Pancreatitis, Diabetes, and Obesity

Like smoking, chronic pancreatitis is a well-accepted risk factor for PDA, with an OR of 2.7 for patients with over 2 years of disease. The OR skyrockets for patients with less than 2 years of chronic pancreatitis (13.6), in large part because the pancreatitis in these patients represents a presenting symptom of PDA, as oppose to a contributing cause.²² A preponderance of the evidence from over a dozen studies suggests that obesity is a mild contributing risk factor for PDA (OR 1 to 1.5). Proposed mechanistic links include hormonal (e.g., insulin and insulin-like growth factor 1 [IGF-1]) and inflammatory influences on pancreatic cells, as well as increased carcinogen exposure related to food consumption.²³ Although a link between type II diabetes mellitus (DM) and pancreatic cancer has been extensively studied, a causal association has not been clearly established. Two meta-analyses have been performed that examined more than 30 studies performed over 4 decades. Type II DM is associated with a twofold risk increase for PDA. Patients with long-standing DM (> 5 years) have a mildly increased risk compared to patients without DM, suggesting that the disease may indeed contribute to tumorigenesis. Similar to obesity, increased levels of insulin and IGF-1 have been implicated. As with chronic pancreatitis, the highest risk for PDA is clearly in patients with recent onset of DM (< 5 years, and particularly within 1 year), suggesting that DM is principally a manifestation of PDA, as opposed to a true risk factor in these patients.^{24,25}

PATHOLOGY AND BIOLOGY

The normal pancreas contains two epithelial cell types: exocrine and endocrine cells. Most of the pancreas is comprised of exocrine

cells, which line an organized ductal network. Acinar cells line the smallest ducts; they synthesize and secrete digestive enzymes. Larger ducts are lined by intercalated duct cells, and secrete bicarbonate and water. Ultimately, the ducts converge into the main pancreatic duct, which drains into the duodenum. The endocrine component makes up just 1% of the pancreas, and consists of islets of Langerhans. These hormone-producing cell clusters are primarily involved with glucose homeostasis. The principal endocrine cell types include the A (alpha), B (beta), and D (delta) cells, which synthesize glucagon, insulin, and somatostatin, respectively. The different cell types are believed to give rise to the different variants of pancreatic neoplasms.

Pancreatic cancer refers to a heterogeneous group of malignant pathologies that originate in the pancreas, and nearly all are epithelial in origin. They are categorized by their gross appearance (solid or cystic), as well as the predominant cell differentiation pattern (ductal, acinar, or endocrine). Primary pancreatic mesenchymal (e.g., sarcomas) and lymphoid neoplasms are exceptionally rare, and will not be reviewed here. Dozens of different epithelial pancreatic neoplasms have been described, but over 85% are the conventional pancreatic (tubular) ductal adenocarcinomas, and more than 98% of cancers fit into one of the following additional diagnoses: solid types, which include pancreatic endocrine neoplasms, acinar cell carcinomas, and pancreatoblastomas; and cystic types, which include mucinous cystic neoplasms, intraductal papillary mucinous neoplasms, and solid-pseudopapillary neoplasms. These diagnoses are typically made based on microscopic appearance, but a diagnosis may be confirmed with immunolabeling of specific proteins. Uncommon variants of ductal adenocarcinoma that are rarely encountered will not be reviewed. These include adeno-squamous carcinoma, colloid noncystic adenocarcinoma, hepatoid carcinoma, signet ring carcinoma, medullary carcinoma, and undifferentiated carcinoma. The classification and nomenclature of pancreatic epithelial neoplasms has been reviewed by Klimstra, Pitman, and Hruban.²⁶

EXOCRINE PANCREATIC CANCERS

Pancreatic Ductal Adenocarcinoma

Although the molecular mechanisms that underlie aggressive PDA biology remain poorly understood, there are certain features of PDA that are unique or defining, and will be highlighted in this section on pathobiology as well as in the Future Directions and Challenges section at the end of the chapter. These include molecular heterogeneity, a tendency for perineural invasion, remarkable tolerance to nutrient deprivation, and abundant stroma.

PDA Pathology

PDAs appear as ill-defined, sclerotic, yellow-white masses on gross inspection. The edges are poorly defined and infiltrative. Histologically, they are characterized by perineural invasion in almost all cases (much more frequently than in other common adenocarcinomas like colon and breast). Microscopic vessel and lymphatic invasion are common, and tumor necrosis is frequently present. Even in localized and resected cases, PDAs are rarely encountered at the T1 stage nor are they well differentiated, which drives home the fact that PDA is seldom diagnosed *early* in the life span of the tumor, at a *curable* stage.²⁷ On light microscopy, the cells typically form infiltrative gland-forming structures, separated from each other by a tenacious desmoplastic reaction. Lymph node spread is present in the majority of resection specimens with localized disease. Immunohistochemical markers typically seen include cytokeratins (e.g., 7, 8, 13, 18, 19), CA19-9, B72.3, CA-125, and DUPAN-2. The nonneoplastic desmoplastic (stromal) component comprises more than 70% of the tumor mass (a higher proportion than other common solid tumors), and is commonly referred to as

Figure 49.1 High-power photographs of PDA. **(A)** PDA containing dense stroma. **(B)** PDA with perineural invasion. **(C)** Intraductal papillary mucinous neoplasms. **(D)** Mucinous cystic neoplasms.

the tumor microenvironment (TME). The stroma consists of an extracellular matrix and numerous cell types, including inflammatory cells, pancreatic stellate cells, endothelial cells, nerve cells, fibroblasts, and myofibroblasts. The stroma is hypovascular with a low vessel density and high interstitial fluid pressure, resulting in a poorly perfused epithelial compartment, and the characteristic *hypodense* appearance on cross-sectional imaging obtained with intravenous contrast. Classic histologic features of PDA are depicted in Figure 49.1.²⁸

The stroma creates a barrier to effective drug delivery²⁹ and is believed to contribute to the overall virulence of the tumor. Sophisticated mathematical modeling reveals that austere conditions in the TME impose profound selection pressures on cancer cells, leading to the generation and dominance of aggressive cancer subclones.³⁰ These subclones are chemoresistant and well adapted to survive extreme conditions present in the TME. Not surprisingly, PDA cells are more resistant to nutrient deprivation than most aggressive cancer types.³¹ There is now a concerted effort to develop strategies to target the tumor microenvironment in PDA (see Future Directions and Challenges).

PDA development follows an adenoma to carcinoma sequence, similar to previous descriptions for colon cancer.³² Precursor lesions are referred to as PanIN lesions (pancreatic intraepithelial neoplasia), and are graded from PanIN-1 to PanIN-3. Early PanIN lesions are common (present 20% of individuals at autopsy³³) and most do not progress to PDA in an individual's lifetime. PanIN-1A lesions are tall columnar cells with abundant mucin; PanIN-1B lesions are similar but have a papillary appearance. PanIN-2 lesions have nuclear abnormalities. PanIN-3 lesions were formerly called carcinoma in situ; they exhibit true cribriforming, budding cells

into lumen, loss of nuclear polarity, and mitoses. PanIN-3 lesions are found in roughly 2% of autopsy specimens from individuals who died from nonpancreatic diseases (Fig. 49.2).³³ The similar lifetime risk of PDA suggests that a high proportion of PanIN-3 lesions develop into clinically significant cancer. Future effective early detection strategies would ideally discover and treat PanIN-3 lesions.²⁸

PDA Genetics

Unlike breast and other cancers, PDA cannot be subgrouped by molecular characteristics at the present time to guide therapy or to inform prognosis. However, whole-exome sequencing of numerous PDAs were performed and provided unprecedented insight into the genetics of PDA.^{34,35} High throughput sequencing data emphasize the molecular complexity of PDA. Out of 24 PDA genomes, 1,327 different genes (~7% of coding genes) were found to have at least one somatic mutation, and 148 different genes had at least two mutations (0.7%).³⁵ There were an average of 60 genetic alterations per tumor, and each PDA had a unique genetic fingerprint. Unfortunately, sequencing studies did not identify any novel high frequency mutated *cancer genes* as promising therapeutic targets. A more practical approach to *personalized therapy* is to group the genetically altered genes into 12 core signaling pathways (e.g., apoptosis, DNA damage, and 10 others), as proposed by Jones et al.³⁵ These pathways are universally dysregulated and therefore may be more realistic therapeutic targets than single genes.³⁵ A separate study found that axon guidance genes were also mutated at a higher rate than what was expected by chance, although the functional importance of these neuron-related genes in cancer is still unknown.³⁴

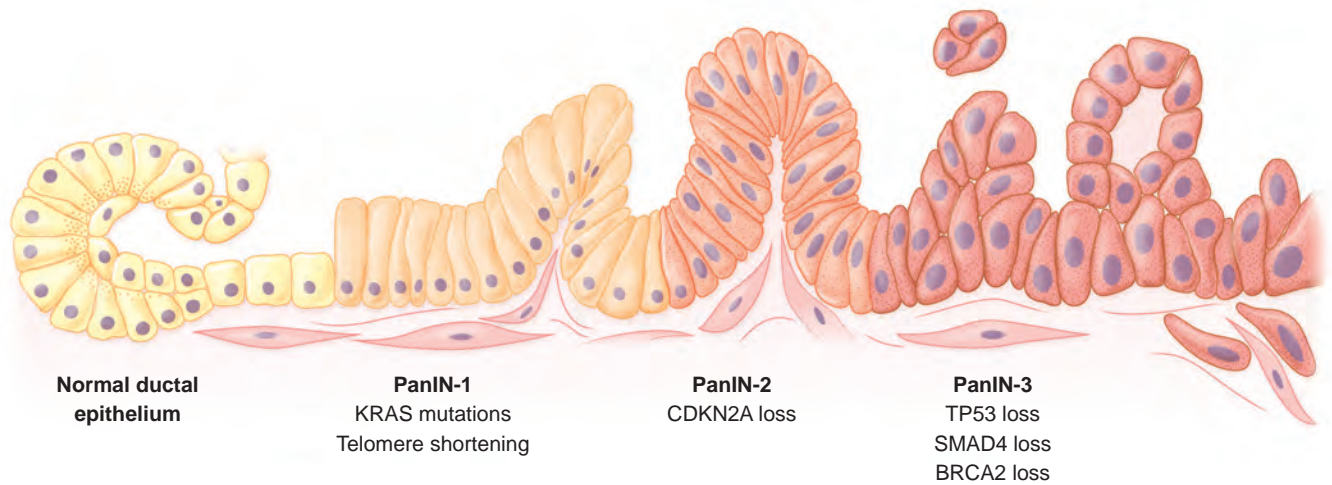

Figure 49.2 PanIN sequence with observed molecular changes. (From Maitra A, Hruban RH. Pancreatic cancer. *Annu Rev Pathol* 2008;3:157–188.)

A genetically altered gene may be categorized as an oncogene (with gain-of-function mutations), a tumor suppressor gene (loss-of-function), or a genome maintenance gene (loss-of-function). For the latter two gene types, both copies of the gene are typically inactivated; one allele is lost by somatic mutation and the other by chromosomal or allelic loss (loss of heterozygosity [LOH]). Oncogenic *Kras* is altered in more than 90% of PDAs, and is usually an early event in tumorigenesis.^{28,35,36} Somatic *Kras* mutations mostly occur in codon 12, and rarely occur in codons 13 and 61.³⁷ The sequence alterations inactivate GTPase function, leaving GTP continuously engaged and the oncogene constitutively activated. Activated *Kras* positively regulates multiple signaling pathways, including the BRAF/mitogen-activated protein kinase (MAPK) pathway (proliferation), phosphatidylinositol 3-kinase (PI3K)/mammalian target of rapamycin (mTOR) (cell growth and survival), and Phospholipase C (PLC)/Protein kinase C (PKC)/Ca⁺⁺ (calcium and second messenger signaling).³⁸ To date, attempts to pharmacologically inhibit *Kras* have been unsuccessful.³⁹ However, because of its early development in nearly all PDAs, the importance of this molecule will continue to preoccupy pancreatic researchers in hopes of finding an effective targeted therapy with a large therapeutic window (see Future Directions section).

The remaining *high frequency* mutated pancreatic cancer genes are tumor suppressor genes. The pattern of frequent allelic loss mutations in PDA due to chromosome instability (losses are more common than gains⁴⁰), promotes a fertile environment of genetic experimentation that favors loss of function mutations. Allelotyping reveals that genetic loss ranges from 17% to 80% of the genome in a given PDA.⁴¹ Allelic loss is nonrandom across the PDA genome; LOH *hot spots* (areas where genetic loss most commonly occurs) harbor the most important tumor suppressor genes in PDA: CDKN2A (9p), TP53 (19p), and SMAD4 (18q).

CDKN2A (p16) is inactivated in roughly 95% of PDAs, either through homozygous deletion (deletion of both alleles), somatic mutation combined with LOH (deletion of one allele), or promoter hypermethylation. Inactivation of the gene abrogates the RB1-mediated G1/S checkpoint in the cell cycle (which allows unchecked inhibition of RB1 by CDK4), promoting cell cycle progression and cancer cell proliferation.^{42,43} TP53 mutations combined with LOH also occur in the majority of PDAs (~75%).⁴⁴ TP53 is a critical component of the DNA damage response. In the face of a cytotoxic stress, TP53 induces cell cycle arrest (at G1 or G2 of the cell cycle), allowing cells to repair their DNA prior to DNA synthesis or mitosis. Thus, TP53 loss contributes to chromosome instability and aneuploidy observed in PDA.⁴⁵ TP53 has been targeted experimentally by reactivating the mutant isoform⁴⁶ or by targeting the G2/M checkpoint with WEE1 inhibitors

(TP53-deficient tumors are particularly dependent on the G2/M checkpoint).⁴⁷ SMAD4/DPC4 is inactivated in roughly half of PDAs through either homozygous deletion or mutation combined with LOH.^{48,49} SMAD4 is part of the transforming growth factor β (TGF β) receptor pathway, and like the other two aforementioned tumor suppressor genes, regulates the cell cycle at the G1/S checkpoint.²⁸ Interestingly, preservation of SMAD4 protein expression is associated with a local predominant progression pattern in PDA, which could be used to guide patient selection for radiotherapy.⁴⁹

A group of genome maintenance genes (BRCA2, PALB2, FANCC, FANCG) involved in the Fanconi anemia DNA repair pathway (mutated in <10% of PDAs) are particularly intriguing because tumors deficient in this pathway are highly susceptible to DNA damaging agents and poly(ADP-ribose) polymerase (PARP) inhibitor therapy.²⁵ Mutations in these genes are often present in the germline, and will be discussed further in the section on genetic syndromes associated with pancreatic cancer.

Analyses of laser capture microdissected pancreatic tissues have elucidated the chronologic sequence of major genetic changes in pancreatic tumorigenesis. Telomere shortening and *Kras* mutations are believed to be the earliest events (PanIN-1)^{50,51}; *p16* loss occurs at the PanIN-2 stage⁵²; and TP53, SMAD4, and BRCA2 inactivation occur later during the PanIN-3 stage (see Fig. 49.2).^{53,54} Major chromosome instability, characterized by large-scale allelic copy number changes, is rarely observed in PanIN lesions, and is principally limited to LOH *hot spots*.^{55–57}

Iacobuzio-Donahue and colleagues⁴⁹ recently launched into pioneering work by extending the molecular progression model of pancreatic cancer to the most advanced stages of disease, through a rapid autopsy program in which primary tumors and paired metastases were sequenced and compared. The investigators distinguished *founder mutations* (those that arise early in tumorigenesis and are present throughout a tumor; about two-thirds of mutations) from *progressor mutations* (mutated in subclonal populations of cells, and absent in the parental clones; about one-third of mutations).⁵⁸ Interestingly, progressor mutations that existed throughout a metastatic deposit were also identified in certain microdissected foci in the primary tumor, but not throughout the primary. This finding demonstrated that parent clones giving rise to specific metastases can actually be defined and mapped in the primary tumor. Although previous sequencing studies highlighted intertumoral heterogeneity, this study was the first to identify intratumoral genetic heterogeneity in PDAs, with profound implications on therapy.

Roughly 10% of PDAs are familial, and only 10% of the familial subgroup are associated with a previously defined genetic syndrome.⁵⁹ Table 49.2 summarizes those familial syndromes and

TABLE 49.2

Familial Disorders Linked to Predisposition to Pancreatic Ductal Adenocarcinoma

Disease	Gene/Pathway	Lifetime Risk
Inherited pancreatitis	SPINK1/PRSS1	40%
Peutz-Jeghers syndrome	LKB1	30%
Familial atypical multiple mole melanoma (FAMMM)	CDKN2A	15%
Hereditary breast and ovarian cancer	BRCA2	5%
Familial breast cancer	PALB2	?
Ataxia telangiectasia	ATM	?
Familial (>3 FDRs)	Unknown	40%
Familial (2 FDRs)	Unknown	10%
Familial (1 FDRs)	Unknown	6%

FDR, first-degree relative.

genetic defects that have been identified in pancreatic cancer kindreds. Hereditary breast and ovarian cancer is the most common familial syndrome, and the Peutz-Jeghers syndrome confers the highest lifetime risk. Importantly, several of the familial syndromes are associated with defects in DNA repair pathways (BRCA2, PALB2), which likely render tumors particularly susceptible to therapy with DNA damaging agents (e.g., mitomycin C, platinum agents) and PARP inhibitors.¹¹ Other genetic predisposition alterations, such as single nucleotide polymorphisms (SNP) likely play a role in cancer risk, but remain to be fully characterized. Ongoing whole-exome sequencing efforts in familial patients will almost certainly uncover additional genetic abnormalities that predispose individuals to PDA.

There are currently no universal guidelines or proven strategies for screening high-risk individuals. The Cancer of the Pancreas Screening (CAPS) project has been the principal mechanism to study this patient population and generate recommendations. In one CAPS study, 225 asymptomatic, high-risk individuals were screened with magnetic resonance imaging (MRI), computed tomography (CT) scans, or endoscopic ultrasound (EUS) and the results were interpreted in a blinded fashion. An abnormality was identified in 92 patients (42%), and 5 were recommended to undergo a pancreatectomy (2%). High-grade dysplasia was present in three out of the five specimens.⁶⁰ These data highlight that while successes are possible, the general yield of screening programs, even in this high-risk group, is relatively low.

Recently, a 49 member multidisciplinary panel made the following recommendations (with varying degrees of agreement amongst panelists): candidates for screening include FDRs of individuals with familial pancreatic cancer (at least two FDRs); patients with Peutz-Jeghers syndrome; and p16, BRCA2, and HNPCC mutation carriers with one affected FDR. There was also consensus that EUS and MRI were the preferred surveillance strategies. Routine surveillance should be performed annually, and suspicious solid masses should be further evaluated by CT scanning. Screening should begin around 50 years of age.⁶¹

Other Aspects of PDA Biology

Genetically engineered mouse models (GEMM) of PDA have provided a valuable research tool to study PDA biology.⁶² The workhorse of pancreatic cancer research in this area has been the conditional *Kras* model, where pancreas-specific promoters are exploited to target oncogenic *Kras* expression exclusively to the pancreas. *Kras* mutant mice develop pancreatic precursor lesions

(e.g., PanIN lesions). Compound mutant mice with an additional genetic abnormality (e.g., mutant TP53 or CDKN2A) develop invasive and metastatic PDA, simulating human PDA. Similarly, *Kras* mutant mice with induced pancreatitis also develop invasive PDA. Genetic variations have also been generated that recapitulate pancreatic cystic tumors (SMAD4 loss or TGF α overexpression). The contributions of these models have been immeasurable. For instance, cell lineage tracing experiments in GEMMs reveal that PDA likely originates from acinar or centroacinar cells, as opposed to ductal cells (i.e., acinar-to-ductal metaplasia). GEMMs are enabling the development of molecular and bioimaging assays to detect late PanIN and early invasive lesions. Because GEMMs develop tumors with a robust stroma compartment, therapeutic strategies targeting the stroma can be tested. Early results suggest that this strategy enhances therapeutic efficacy of standard cytotoxic therapy. Finally, these models can be used to test and refine chemoprevention strategies before moving to humans.

Cancer genetics (e.g., mutations) have been prioritized over the last few decades in PDA cancer research, in large part because of the reproducibility of the findings and because the genetic model of tumorigenesis is straightforward and accepted. However, it is now clear that other molecular changes are also paramount for PDA development and maintenance. These include epigenetic abnormalities (methylation and histone modification), transcriptional regulation, and posttranscriptional regulation (microRNAs and RNA binding proteins).²⁸

Less Common Pancreatic Cancers

Acinar Cell Carcinoma

Acinar cell carcinomas may have a slightly better prognosis (median survival of 33 months) than conventional PDA. The presentation is similar, except that patients may occasionally develop a paraneoplastic syndrome related to lipase hypersecretion, leading to subcutaneous fat necrosis and polyarthralgia. Microscopically, tumors grow in a trabecular pattern with minimal intervening stroma. Immunohistochemical confirmation is made with positive labeling for pancreatic enzymes (e.g., lipase, trypsin, chymotrypsin, amylase).⁶³ Cystic variants have been reported as well, and described as acinar cystadenoma or cystadenocarcinoma.²⁶ Twice the number of somatic mutations per tumor is present (~130 per tumor) compared to PDA, and allelic loss is comparable (27% fractional loss). Whole-exome sequencing did not reveal a consistent genetic pattern; no gene was mutated in more than 30% of cancers, and mutant genes previously identified in diverse pancreatic tumor types (e.g., TP53, SMAD4, RNF43, MEN1, GNAS) and nonpancreatic tumors (e.g., BRAF, PTEN, RB1, APC) were identified. Additionally, some mutant familial genes were identified (e.g., ATM, BRCA2, PALB2), suggesting that this tumor may arise in a familial pattern.⁶⁴ Interestingly, no *Kras* mutations were identified.

Pancreatoblastoma

Pancreatoblastoma is the most common pancreatic malignancy in children and usually occurs in the first 8 years of life. These tumors have been associated with the Beckwith-Wiedemann and familial adenomatous polyposis syndromes. Elevated levels of serum α -fetoprotein and hormones have been described. Cures are often achievable with resection in children, although one-third of patients present with metastatic disease. Cases have been reported in adults as well, with survival after resection that is comparable to conventional PDA.⁶⁵ Microscopically, these tumors contain acinar cells, but other cell types (e.g., neuroendocrine, ductal) are often present. Pancreatoblastomas have been whole-exome sequenced in only two adult cases.⁶⁴ These tumors acquire relatively few mutations (~15 per tumor), and SMAD4 and CTNNB1 are typical. *Kras* mutations have not been reported.

Intraductal Papillary Mucinous Neoplasms

Intraductal papillary mucinous neoplasms (IPMN) are mucin-producing cystic neoplasms that arise from (and therefore communicate with) pancreatic ducts.⁶⁶ Similar to PanIN lesions, they follow a progression pattern: low-grade dysplasia, moderate-grade dysplasia, high-grade dysplasia, and frank invasive carcinoma. Benign IPMNs are subgrouped according to their papillary appearance on microscopy (see Fig. 49.1), with each type associated with a particular mucin expression pattern: intestinal (MUC5AC, MUC2), gastric-foveolar (MUC5AC, MUC6), pancreatobiliary (MUC5AC, MUC1), and intraductal oncocytic neoplasm (MUC1, MUC6). Clinically, IPMNs are classified as involving the side-branch ducts or the main-pancreatic duct, with some tumors involving both of these. IPMNs are the most common pancreatic cystic neoplasms and with increased usage of high-resolution cross-sectional imaging, are believed to develop in roughly 1% to 5% of the general population.⁶⁷ Although all benign IPMNs are technically *pre-malignant*, there is a wide range of malignant potential amongst encountered cysts. For instance, main duct IPMNs harbor associated cancers 40% of the time, whereas small side-branched IPMNs without any concerning radiographic features have a cancer risk closer to 5% or less.⁶⁸ Thus, there has been considerable effort to try to determine which IPMNs harbor invasive cancer or are at highest risk for malignant transformation and warrant resection. The Sendai guidelines recommend resection for IPMNs that are either symptomatic, >3 cm in diameter, contain solid components (e.g., mural nodules), have malignant cells on cytology, or involve the main pancreatic duct.⁶⁸ Invasive cancer associated with IPMNs are most commonly either tubular (conventional PDA) or colloid subtypes. The former is typically more aggressive and develops from pancreatobiliary IPMNs, whereas the latter usually develops from intestinal subtypes. Although IPMN-associated cancers have a more favorable prognosis than conventional PDA, this has been attributed to the lower stage at diagnosis; when matched stage for stage, the two pancreatic cancer types are associated with similar outcomes.⁶⁹ Moreover, a recent multi-institution analysis of IPMNs with small foci of invasion (all <2 cm invasive component) indicates a significant recurrence risk (~20%) regardless of the size of the invasive component (Jordan M. Winter, MD, unpublished, July 2014).

Whole-exome sequencing of IPMN lesions revealed roughly half the number of mutations (~27 per tumor) compared to PDA. There was a high incidence of RNF43 mutations, which is a tumor suppressor with E3 ubiquitin ligase activity (involved in protein degradation).⁷⁰ Additionally, Kras and GNAS mutations occurred with high frequency.

Mucinous Cystic Neoplasms

Mucinous cystic neoplasms (MCN) are typically large cysts lined by tall, columnar epithelium (see Fig. 49.1). Benign MCNs are categorized similar to IPMNs from low- to high-grade dysplasia, and roughly one-third of cases harbor invasive cancer. Additionally, RNF43 and Kras mutations are frequently present (as with IPMNs). Distinguishing features of MCNs (from IPMNs) include a large predominance in woman, the cysts are typically localized on the left side of the pancreas, ovarian stroma underlying the epithelial component is pathognomonic (even in men), there is no communication with the pancreatic duct, and GNAS mutations have not been identified.^{26,70}

Solid-Pseudopapillary Neoplasms

Solid-pseudopapillary neoplasms (SPNs) solid and cystic tumors are eponymously referred to as Hamoudi or Franz tumors. They typically occur in young women and may arise throughout the gland. Histologically, they consist of noncohesive polygonal cells that form solid masses, but develop cystic components over time with frequent intracystic hemorrhage. The tumors are considered

low-grade malignancies, with a 10% risk of lymph node spread in resected specimens, and a 95% lifetime recurrence-free survival rate after resection.⁷¹ SPNs develop fewer than five somatic mutations per tumor, but virtually all SPNs harbor CTNNB1 (β -catenin) mutations. This molecular abnormality is believed to contribute to the poor cohesion between cells apparent on microscopy (wild type β -catenin interacts with E-cadherin at cell-cell junctions).

ENDOCRINE PANCREATIC CANCERS

The classification of pancreatic neuroendocrine tumors (PNET) has been challenging based on the heterogenous biology of this tumor type. Recent staging systems have been adopted based on size and lymph node metastases, with different versions in the United States (AJCC 7th ed. 2010, same as exocrine pancreatic cancer) and Europe (European Neuroendocrine Tumor Society [ENETS]).⁷² The ENETS system also considers biologic parameters and has simplified the World Health Organization classification according to the following scheme: G1 (well differentiated, <2 mitoses per 10 High power field (HPF), <3% KI67 index); G2 (well differentiated, intermediate grade: 2 to 20 mitoses per 10 HPF, 3% to 20% KI67 index); and G3 (high grade or poorly differentiated: >20 mitoses per 10 HPF, >20% KI67 index).⁷³ Typically, G1 tumors are considered benign and cured with resection, whereas G2 tumors are considered malignant. However, the distinction (benign versus malignant) is not always clear. Older studies observed that half of PNETs were nonfunctional and half were functional due to the presence of measurable hormones in serum.⁷⁴ The balance has shifted dramatically toward nonfunctional tumors being more common, in large part due to small, incidentally discovered PNETs identified on cross-sectional imaging obtained for nonpancreatic reasons.

Pancreatic neuroendocrine cancers have an incidence of roughly 0.2 out of 100,000 (versus 12 out of 100,000 for PDAs), yet autopsy studies show that small PNETs are very common (~10% of deceased individuals).⁷⁵ They comprise roughly 5% of all resected pancreatic cancers (on par with IPMN associated cancers).²⁷ PNETs are typically well demarcated and hypervascular. Therefore, they focally enhance on the arterial phase in imaging studies with intravenous contrast. Microscopically, neoplastic cells are arranged in a nested fashion with a high density of intratumoral microvessels (in contrast to PDA). The majority of well-differentiated PNETs have an indolent course and are cured with surgery alone. Even patients with metastatic disease have a 5-year survival around 50%.⁷² Insulinomas are the most common functional PNETs (30% to 45%) and symptoms are associated with excessive endogenous insulin production (Whipple triad: documented hypoglycemia, symptoms of hypoglycemia, improved symptoms with correction of hypoglycemia).⁷⁶ Gastrinomas comprise roughly 20% of functional PNETs, and cause peptic ulcer disease and diarrhea from hypergastrinemia. Less common functional PNETs include glucagonomas (associated with glucose intolerance and migratory necrolytic erythema), VIPomas (watery diarrhea), and somatostatinomas (steatorrhea, diabetes mellitus, and gallstones). Familial syndromes associated with the development of PNETs include multiple endocrine neoplasia 1 (MEN1 gene), von Hippel-Lindau disease (VHL), neurofibromatosis (NF1), and tuberous sclerosis (TSC1 or TSC2).

The genetic landscape of PNETs has now been defined through whole-exome sequencing.⁷⁷ Compared to PDAs, there are fewer somatic mutations per tumor (~16). Kras mutations have not been observed. Commonly mutated genes included MEN1 (44% of PNETs), chromatin remodeling genes (43%: DAXX and ATRX), and mTOR pathway genes (15%: phosphatase and tensin homolog [PTEN], PIK3CA, and TSC2). This latter gene group likely renders many PNETs vulnerable to systemic targeted therapy using mTOR inhibitors. Although surgery is the principal therapy for local disease, treatment options have greatly expanded

for advanced disease, and include local liver-directed therapies (radiofrequency ablation), regional liver-directed therapies (bland, chemo, and radioembolization), and systemic therapies (cytotoxic drugs, targeted agents, somatostatin analogs including radio-labeled drugs). The complex management of PNETs is discussed in other reviews on the subject.⁷⁸

STAGE I AND II: LOCALIZED PANCREATIC DUCTAL ADENOCARCINOMA

Anatomy

The evaluation and treatment of localized pancreatic cancer requires a strong understanding of the anatomy of the pancreas and nearby structures. The pancreas is an elongated gland in the retroperitoneum that crosses the midline at the L2 spinal level (Fig. 49.3). It is bounded anteriorly by the stomach and posteriorly by the inferior vena cava, aorta, left adrenal gland, and left kidney. The descriptive anatomy of the gland is grossly separated into four components. The head is the right-most portion, and sits within the duodenal C-loop. It includes the uncinate process, which projects inferomedially, extending to the right lateral border of the superior mesenteric artery. The common bile duct runs

within (or rarely just posterior) to the pancreatic head and enters the duodenum at the ampulla of Vater with the main pancreatic duct. Moving leftward, the neck of the pancreas lies anterior to the superior mesenteric vein–portal vein axis. The superior mesenteric vessels run posterior to the pancreatic neck, and course inferiorly across the anterior border of the third portion of the duodenum. The body of the pancreas extends to the left of the superior mesenteric vessels. The gland transitions distally into the pancreatic tail anterior to the left kidney, and courses toward the splenic hilum.

Presentation

The most common presenting symptoms associated with PDA located in the right side of the pancreas (head, neck, or uncinate process) include jaundice (75%), weight loss (50%), abdominal pain (40%), or nausea (10%).²⁷ Jaundice occurs as a result of obstruction of the common bile duct and is often associated with pruritus. Other symptoms or findings associated with an obstructed bile duct include acholic stools and tea-colored urine. An obstructed pancreatic duct may induce acute pancreatitis and result in exocrine insufficiency associated with steatorrhea. Patients with left-sided PDAs (body or tail) typically experience abdominal pain, back pain, and nausea. New onset DM (within 1 year of diagnosis) occurs in roughly 10% of patients with PDA, based on our own institutional experience and others (unpublished).⁷⁹

Evaluation and Assessing Resectability

Although periampullary cancer (adenocarcinoma of the pancreas, ampulla of Vater, bile duct, or periampullary duodenum) should be considered in any patient who presents with a conjugated hyperbilirubinemia, the likelihood is highest in older patients (e.g., >55 years). In individuals with an expected pancreatic cancer, a thorough history and physical should be performed, followed by appropriate imaging for staging and to assess resectability. Critical findings on physical exam include scleral icterus, jaundice, and lymphadenopathy (e.g., Sister Mary Joseph or Virchow nodes). A chest x-ray or chest CT scan is performed to assess for pulmonary metastases and as a baseline study. Either a high-quality MRI or CT scan of the abdomen is performed to evaluate the pancreas and measure the extent of disease. We typically prefer CT for its superior resolution and detailed depiction of the relevant vasculature. Water is administered as oral contrast, and nonionic intravenous contrast is rapidly injected. Slices are captured at 1-mm intervals from the diaphragm to the iliac crests at three different times or phases: early arterial, late arterial, and venous. Multiplanar reformatting and three-dimensional (3D) surface rendering is performed during the early arterial and venous phases (Fig. 49.4).⁸⁰ Positron-emission tomography (PET)/CT scans do

not add much additional value and are not routinely performed in the initial assessment for resectability.

Resection is attempted if (1) patients are medically fit for a pancreatectomy, (2) there is no evidence of metastases, and (3) patients are believed to have *resectable* disease. Resectability is ultimately decided by the operating surgeon, but general guidelines have been proposed and are based on the likelihood of achieving a complete, margin-negative resection.^{81,82} Resectability equates to a high probability of an R₀ resection; borderline resectability equates to a likely result of an R₁ resection (positive microscopic margins); and unresectable (or locally advanced) PDA is likely to result in R₂ resection (residual macroscopic disease). Resectable lesions do not invade the superior mesenteric artery (SMA), celiac axis (CA), common hepatic artery (CHA), or superior mesenteric–portal vein axis (SMV-PV). In contrast, locally advanced lesions encase (i.e., >180° invasion) any of the previously mentioned arteries or occlude the SMV-PV such that no reconstructive options remain. Borderline resectable lesions involve the visceral vessels to a lesser extent; they can abut the visceral arteries (<180° invasion), distort the visceral veins, or even occlude the SMV-PV, but with venous reconstruction still technically feasible (Table 49.3).⁸³ Most pancreatic surgeons offer patients with resectable lesions an attempt at resection (although some centers advocate neoadjuvant treatment prior to resection even for resectable lesions⁸⁴). Patients with locally advanced lesions are recommended

TABLE 49.3

Criteria for Resectability

Vessel	Resectable	Borderline Resectable	Locally Advanced
	R ₀ Resection Likely	R ₁ Resection Likely	R ₂ Resection Likely
SMA	No abutment	Tumor abutment	Tumor encasement
Celiac axis/ hepatic artery	No abutment	Tumor abutment	Tumor encasement
SMV–PV	Abutment may be present but no vein distortion	Vein Distortion or short-segment occlusion with suitable vessel above and below	Occluded and no technical option for reconstruction

Note: R₀ = gross total resection; histologically negative margins.

R₁ resection = gross total resection; one or more histologically positive margins.

R₂ resection = subtotal resection, visible tumor unresected.

Abutment is $\leq 180^\circ$ vessel circumference; encasement is $> 180^\circ$ vessel circumference.

SMA, superior mesenteric artery; SMV–PV, superior mesenteric vein–portal vein.

Modified from Varadhachary GR, Tamm EP, Abbruzzese JL, et al. Borderline resectable pancreatic cancer: definitions, management, and role of preoperative therapy. *Ann Surg Oncol* 2006;13:1035–1046.

to undergo palliative treatment without the intent to cure. Considerable debate remains for borderline PDAs; resection may be offered, but increasingly, neoadjuvant treatment is recommended for even abutment or narrowing of the SMV–PV.⁸¹ Neoadjuvant chemotherapy (\pm radiation) can facilitate resection, and may improve the likelihood of a complete resection with negative margins, even in the absence of a radiographic response.⁸⁵

Obtaining a tissue diagnosis is not essential for all cases. Indications include instances when (1) neoadjuvant treatment is advised or (2) the pretest probability of an alternative diagnosis is considerable (e.g., suspicion for benign causes of pancreatitis, medically managed neoplasms such as lymphoma, or a benign stricture). In these instances, an EUS with fine-needle aspiration (FNA) biopsy is an effective method for obtaining tissue and has an accuracy in excess of 90%.⁸⁶ When the diagnosis is clear based on imaging and history, it is appropriate to proceed to attempted resection without a preoperative tissue diagnosis. Similarly, placement of an endoscopic biliary stent is frequently performed in jaundiced patients preoperatively, but is essential in only selected cases. A multicenter prospective and randomized trial compared routine preoperative biliary drainage with delayed resection to early surgery without stenting in jaundiced patients with pancreatic cancer. Serious complications were increased nearly twofold in the routine biliary drainage group (74% versus 39%; $p < 0.001$), suggesting that biliary decompression be reserved for jaundiced patients unable to undergo resection in a short-time frame (1 to 2 weeks).⁸⁶ A pancreaticoduodenectomy is safely performed, even when the total bilirubin is markedly elevated. Patients, who are otherwise healthy, with normal renal function and clotting parameters will usually tolerate a safely performed pancreaticoduodenectomy with a total bilirubin as high as 20 mg/dL.

Surgery

Technical aspects of a pancreatectomy are detailed elsewhere and are well beyond the scope of this chapter, hence will only be reviewed briefly here. For right-sided pancreatic cancers, a pancreaticoduodenectomy (PD) is performed. The specimen includes the gallbladder, duodenum, head of the pancreas (the pancreatic transection typically is at the level of the neck), proximal jejunum, and distal common bile duct. The most proximal retained jejunum is brought up into the right upper quadrant, and three anastomoses to the pancreas remnant, common hepatic duct, and proximal duodenum (or stomach) are performed (Fig. 49.5A). A distal pancreatectomy for PDA involves resection of the pancreatic body and tail, with an en bloc splenectomy performed to ensure a proper lymphadenectomy. The transected surface of the

pancreatic remnant is closed with suture (Fig. 49.5B) or staples. A central pancreatectomy or local excision for a PDA is seldom if ever performed for PDA due to inadequate lymph node harvest.

A minimally invasive pancreatectomy using laparoscopy or a robotic-assisted approach may be safely performed. Although a minimally invasive approach is more common for benign and premalignant lesions, a presumed diagnosis of PDA is not a contraindication.⁸⁷ A meta-analysis comparing open versus laparoscopic distal pancreatectomies for PDA revealed similar oncologic and pathologic outcomes in the two groups. Patients undergoing laparoscopy had a shorter postoperative stay by 4 days, less blood loss, and fewer surgical site infections.⁸⁸ Importantly, studies comparing the two techniques have not been prospective and randomized, and are, therefore, all subject to selection bias, with the more difficult resections falling into the open group. Although most high-volume pancreatic centers offer minimally invasive left-sided resections, laparoscopic PD is more technically challenging, and only a handful of centers have a significant experience.⁸⁹ These centers report comparable outcomes with minimally invasive versus open pancreatic surgery in their own experience, although an advantage of laparoscopic PD has not yet been proven in a prospective and randomized study.

International Study Group of Pancreatic Surgery Contributions

Surgically related mortality after PD has improved dramatically over the last 3 decades, and is lower than 5% at most high volume centers.²⁷ However, morbidity remains high ($\sim 40\%$). The most common complications include pancreatic leak (20%), delayed gastric emptying (15%), and wound infection (10%). Bile and duodenal leaks occur in roughly 3% and 1% of patients, respectively.²⁷ The greatest limitation to studies focused on pancreatectomy-related complications has been a lack of standard definitions across institutions, making comparisons between institutions' reports difficult. The formation of an International Study Group of Pancreatic Surgery (ISGPS) to address this issue has been a great advance in pancreatic surgery-related outcomes research. The group has published consensus criteria and definitions for complication grading on the following pancreatic-specific morbidities: postoperative pancreatic fistula (leak),⁹⁰ delayed gastric emptying,⁹¹ and postpancreatectomy hemorrhage.⁹² In addition, the group established concrete guidelines on reporting features and management of the pancreatic remnant/anastomosis (e.g., duct size, gland texture, mobilization distance, type of anastomosis, suture used, use of stent).⁹³ Definitions of postpancreatectomy-related mortality, bile leak,⁹⁴ and wound infection also vary in the literature, and

Jejunum anastomosed to:

1. Pancreas
2. Common hepatic duct
3. Proximal duodenum or stomach

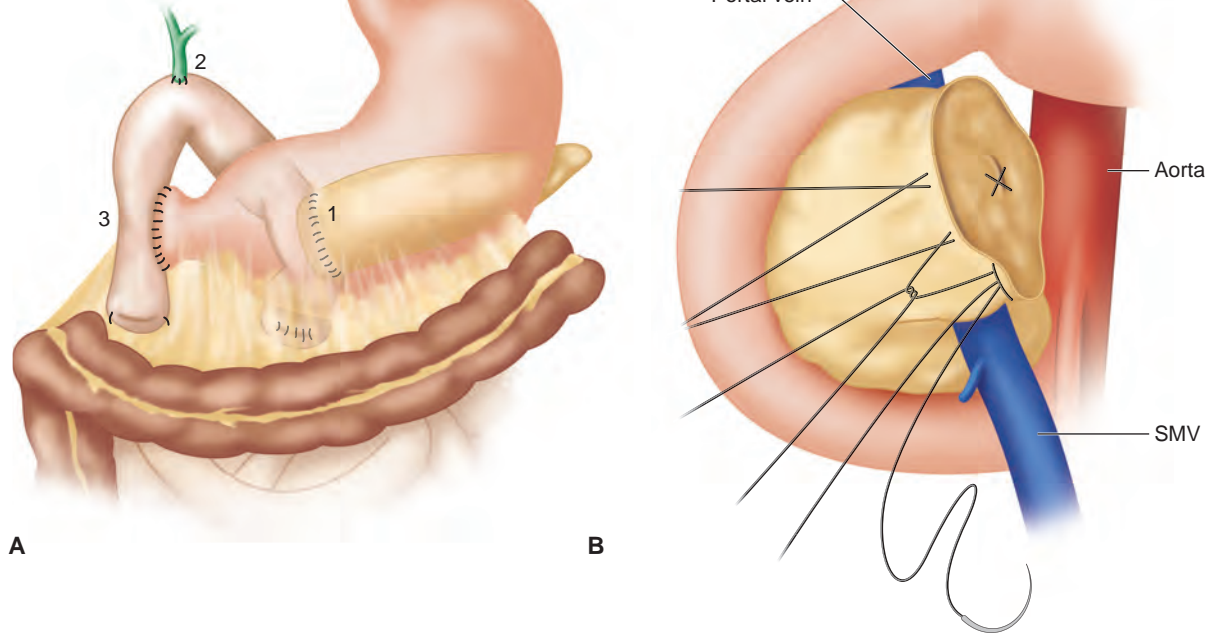

Figure 49.5 (A) Standard reconstruction after a pancreaticoduodenectomy, with an end-to-side pancreaticojejunostomy, an end-to-side hepatic jejunostomy, and a retro-colic and end-to-side duodenojejunosomy. (B) Suture closure of the pancreatic remnant after distal pancreatectomy.

a strategy to standardize terms and complication grading for these outcomes would enhance the surgical literature.

Surgical Trials

There have been numerous prospective and randomized surgical trials that have shaped the surgical management of PDA. A trial unique to PDA, compared to other common cancers, is a study demonstrating superiority of resection over best nonoperative therapy for the management of resectable disease.⁹⁵ A total of 42 patients in Japan with resectable PDA were randomized to either standard pancreatectomy without adjuvant treatment or to chemoradiation alone (50.4 Gy with continuous fluorouracil [5-FU] at 200 mg/m² per day) without surgery. Randomization occurred at laparotomy and patients randomized to chemoradiation had only an open biopsy and abdominal closure. The only multivariate predictor of survival in the study was the treatment group (hazard ratio [HR] = 0.4; $p = 0.02$), with the group undergoing resecting having superior survival (median overall survival (OS), 13 versus 9 months).

Pancreaticoduodenectomy

A comprehensive list of surgical trials in patients undergoing pancreaticoduodenectomy is provided in Table 49.4. Regarding technical aspects of the operation, one of the more studied questions compares pylorus preserving pancreaticoduodenectomy (PPPD) to distal gastrectomy plus pancreaticoduodenectomy (classic PD).⁹⁶⁻¹⁰² Karanicolas et al.⁹⁷ performed a meta-analysis of six randomized trials including 574 patients. PPPD was associated with a reduced operative time by more than 1 hour ($p < 0.001$), less blood loss (284 mL; $p < 0.001$), and fewer blood transfusions. There was a nonsignificant trend toward improved mortality in the same direction (0.4; $p = 0.09$). There was not a significant difference in delayed gastric emptying. Multiple randomized studies have also

examined the location of the enteroenterostomy (antecolic versus retrocolic), and no significant differences were observed.¹⁰³⁻¹⁰⁷

A postoperative pancreatic fistula (POPF) remains the most challenging complication after PD. Clinically significant leaks (e.g., requiring treatment intervention) occur in roughly 10% of cases. Risk factors include soft pancreatic texture, a fatty pancreas, a small pancreatic duct, high intraoperative blood loss, and a high postoperative serum amylase level.^{108,109} Numerous randomized trials have attempted to reduce the pancreatic leak rate, although few have succeeded. Ineffective interventions include fibrin glue,^{110,111} octreotide,¹¹²⁻¹¹⁹ and internal pancreatic stenting.²⁷ Mixed results have been reported with pancreaticogastrostomy (versus standard pancreaticojejunostomy).¹²⁰⁻¹²⁶ The pancreaticojejunostomy *technique* was recently examined, comparing a two-layered invagination technique with interrupted outer stitches and a continuous inner layer, against a duct-to-mucosa technique. The pancreatic leak rate was more than twofold higher with the latter approach (7% grade B/C versus 17%; $p = 0.03$).¹²⁷ A binding pancreaticojejunostomy (versus invagination) is a second technique shown to have a decreased pancreatic leak rate. With this technique, an end-to-end pancreaticojejunostomy is performed; 3 cm of the pancreatic remnant is mobilized and telescoped within the jejunum. No leaks were observed in 106 patients in the latter group, although these data have not yet been replicated.¹²⁸ Interestingly, there now have been three randomized trials showing a lower pancreatic leak rate associated with external pancreatic duct stenting (the pancreatic duct stent is brought out through the bowel and skin as a drain),¹²⁹⁻¹³¹ whereas a fourth study revealed no benefit.¹³² In the past, trials using somatostatin or its analogs have had mixed outcomes in lowering pancreatic leak rates. Recently, a phase III trial using pasireotide (SOM230, a potent somatostatin analog) was completed at Memorial Sloan-Kettering Cancer Center, and revealed a statistically significant lower pancreatic leak rate in patients receiving subcutaneous injections of the study drug

TPN, total parenteral nutrition; PJ, pancreaticojejunostomy; POPF, postoperative pancreatic fistula; IVF, intravenous fluid; MPD, main pancreatic duct; PG, pancreaticogastrostomy; DJ, duodenojejunostomy; DGE, delayed gastric emptying; PPPD, pylorus preserving pancreaticoduodenectomy.

(Peter J. Allen, email communication, January 2014). Roux-en-Y reconstruction performed to isolate the pancreaticojejunostomy (PJ) from the other two anastomoses did not decrease the overall leak rate, but the proportion of clinically significant leaks was substantially reduced (74% versus 29% of all leaks; $p = 0.01$).¹³³

In addition to these important technical trials relevant to the management of right-sided pancreatic neoplasms, other studies have informed the management of patients undergoing PD. A group of studies established that a radical retroperitoneal lymphadenectomy does not confer improved cancer-specific survival (four randomized trials).¹³⁴⁻¹³⁷ Additionally, routine adjuvant parenteral nutrition has proven to be detrimental.¹³⁸ A previous single-institution randomized trial suggested that routine nondrainage after a pancreatic resection is safe,¹³⁹ whereas a recent multi-institution and randomized study revealed a much higher mortality rate in patients without drains,¹⁴⁰ leaving this issue unresolved.

Distal Pancreatectomy

A distal pancreatectomy and splenectomy for left-sided PDA is a simpler operation than pancreaticoduodenectomy, yet also carries significant risk. POPF is the principal morbidity associated with distal pancreatectomy. Clinically significant leaks occur in roughly 10% of cases. In 10% to 20% of cases, a leak is appreciable as amylase-rich fluid in surgical drains, but does not add morbidity. There are now roughly a half-dozen randomized clinical trials examining the effect of pancreatic stump management on POPF, ranging from staplers to mattress sutures. In summary, no positive interventions have been discovered. The DISPACT trial was the largest of these trials. This European multi-institution study analyzed 352 patients, and compared stapled and hand-sewn closures. The pancreatic leak rate was roughly 30% in both groups ($p = 0.56$).¹⁴¹ Fibrin sealant and falciform ligament patches have also been tested, with no observed benefit.^{142, 143} Interestingly, ultrasonic dissection of the pancreas with ligation of all visualized ducts in nonfibrotic glands was associated with improved pancreatic leak rates compared to conventional division and suturing ($n = 58$, 4% versus 26%, $p = 0.02$). Roughly 20 4-0 silk ligatures were used per neck transection in the ultrasonic dissection group, and transection took 10 extra minutes, on average.¹⁴⁴

Palliative Surgery

There have been five randomized trials directly comparing hepaticojejunostomy with endoscopic or percutaneous biliary decompression for patients with malignant periampullary obstruction.¹⁴⁵

A meta-analysis revealed that OS is the same between the groups, although total hospital days after randomization was twofold more in the stenting group, principally related to recurrent biliary obstruction requiring intervention. The authors recommend that for patients projected to live more than 6 months, a surgical biliary (as well as gastric bypass) be considered. Two separate randomized studies have demonstrated that prophylactic gastrojejunostomy in nonobstructed patients decreased the absolute risk of subsequent gastric outlet obstruction by roughly 20%, but did not affect OS.^{146, 147} Finally, there is evidence that celiac neurolysis with alcohol injected at laparotomy in patients with unresectable disease improves quality of life and OS.¹⁴⁸

Operative and Surgical Pathology Reporting

Just as the ISGPS has sought to standardize complication reporting, there have been efforts to standardize operative and pathology reporting to facilitate collaboration between institutions, establish a minimum standard of quality, and provide consistency to the literature. With regard to the operative dictation, a description of the clinical stage (relationship to mesenteric vessels and evidence of metastatic disease) is important. Specific mention of the liver, peritoneum, and small intestines is necessary. Blood loss and the need for transfusion are recorded. The surgical technique used to dissect the uncinate process should be described, as well as the management of the SMA and SMV (e.g., were they skeletonized? resected? the method of visceral vessel repair?). The anastomotic techniques need to be described. The important elements of the pancreaticojejunostomy have been addressed by the ISGPS, as mentioned previously.⁹³ If a frozen section analysis was performed, the results should be stated. Similarly, any gross residual disease must be reported.¹⁴⁹

Standards for pathology reporting have been established by the College of American Pathologists, and protocols are available at the Web site (<http://www.cap.org/apps/cap.portal>). On the pathology review, tumor site (e.g., head, uncinate, body, tail), maximum tumor diameter (in centimeters), histologic type or subtype, and histologic grade (well, moderate, or poor) are provided. Extension into extrapancreatic tissue is described. Margins are assessed (e.g., involvement or distance), including the uncinate, pancreatic neck, common bile duct, and duodenum. The distance to the margin (in millimeters) from the tumor should be stated. The posterior pancreatic surface margin is also reported, although this is not a transected or surgical margin. Microscopic invasion of the lymphatics, small vessels, and nerves are indicated. The TNM stage and the component elements are provided according to the

AJCC 7th edition staging system. A minimum of 12 lymph nodes should be evaluated. Treatment effect is described if the patient has received neoadjuvant therapy.

Assessing Prognosis

Although PDA is widely viewed as an aggressive cancer, like other common cancers, tumors display a wide range of biology. The median survival after resection for PDA is around 18 months in large series²⁷; roughly 20% of patients survive more than 5 years, and a comparable number suffer cancer-specific mortality within just 1 year of surgery.⁵ There would be substantial value in accurately predicting patients' cancer-specific outcome; at the present time, there are no reliable tests to predict prognosis. The most frequently considered adverse prognostic factors include conventional pathologic features (lymph node metastases, poor differentiation, tumor size >3cm, and positive resection margins). The approximate proportions of resected PDAs that fulfill each criterion are 75%, 40%, 50%, and 40%, respectively.²⁷ It must be remembered that each of these individual prognostic factors are weak predictors of outcome, with multivariate Cox proportional hazards ratios only around 1.5. Winter et al.,¹⁶² studied 137 patients who underwent resection for PDA and died within 1 year from their disease or survived more than 30 months (patients with intermediate survival were excluded). Adverse pathologic features were frequently present in long-term survivors; for instance, 65% of patients in the long survivor group had lymph node metastases in the resected specimen. Conversely, lymph node metastases were not detected in 17% of the short survivor group, yet they still recurred early after resection and succumbed to their disease.

Perhaps the most robust prognostic marker routinely used in patients with localized and resectable PDA is the *postoperative* CA 19-9 level. CA 19-9 is a high-molecular-weight glycolipid that is a sialylated derivative of the Lewis a antigen (normally expressed by epithelial cells and absorbed onto the surface of erythrocytes). The oligosaccharide epitope is also present on mucins secreted by pancreatic cancer cells and detectable in the serum. A markedly elevated *preoperative* CA 19-9 level has some prognostic value (on par with conventional pathologic features). *Preoperative* CA 19-9 has also been used by some surgeons as a predictor of unresectable disease when the lesion appears resectable on imaging. Roughly 30% of patients with serum values above 300 U/mL were found to have a contraindication to resection on staging laparoscopy.¹⁵⁰ However, preoperative CA 19-9 is particularly limited in patients with biliary obstruction because the antigen is falsely elevated in this setting.¹⁵¹⁻¹⁵³ In addition, the sensitivity suffers because 5% to 10% of the population are unable to express CA 19-9 due to Lewis antigen variability (related to the presence or absence of a fucosyltransferase).¹⁵⁴⁻¹⁵⁶ As noted previously, CA 19-9 is most informative after resection when biliary obstruction is no longer a confounding variable and there has been macroscopic clearance of the disease. In a landmark ad hoc analysis of the Radiation Therapy Oncology Group (RTOG) 9704 adjuvant trial, an elevated postoperative CA 19-9 level (≥ 180 U/mL, drawn 1 to 2 months after resection) was associated with a multivariate proportional HR of 3.6.¹⁵⁴ Interestingly, Lewis antigen-negative individuals (who cannot express elevated serum CA 19-9) had the same survival as patients with low CA 19-9 levels for unclear reasons.

Patterns of Failure

Although OS after resection for PDA is roughly 18 months,²⁷ patients typically recur by 1 year,¹⁵⁹ indicating a short survival time once a recurrence is detected (comparable in survival to patients with metastatic disease). Recurrences have been reported in virtually every organ site, but most commonly occur in the retroperitoneum (57%), liver (51%), peritoneum (35%), and lung (15%). Interestingly, lung recurrences are typically delayed, and rarely

occur early after resection. A study of recurrence patterns out of Memorial Sloan-Kettering revealed that 12% of resected patients developed a local-only recurrence pattern; 33% had metastatic disease only and 46% had both local and metastatic disease (recurrence status was unknown in the remaining patients).¹⁶⁰

Identifying biomarkers to predict patterns of recurrence could help select the patients who are most likely to benefit from intensive local therapy (radiation). The most intriguing biomarker to date in this area of research has been SMAD4. A study of pancreatic adenocarcinomas from an autopsy series (n = 65) revealed that a local predominant pattern was associated with intact SMAD4 expression (7 of 9 cases), whereas a disseminated pattern was associated with absent SMAD4 expression (16 of 22 cases).⁴⁹ This pattern was confirmed in tissue samples of patients from a phase II trial of locally advanced PDA.¹⁶¹ Out of 15 patients with SMAD4-positive tumors, 11 had progression in a local-predominant pattern. In contrast, 10 of 14 patients with absent SMAD4 had significant distant spread. These studies suggest that patients having tumors with intact SMAD4 are most likely to benefit from radiation, whereas those patients with absent SMAD4 should only receive systemic therapy. However, a study of resected PDA samples revealed that resection alters the natural history of PDA recurrence, such that SMAD4 status is no longer predictive of recurrence pattern in this setting.¹⁶⁰ Other biomarkers¹⁶² were examined as part of that study, and MUC1 expression was associated with a metastatic recurrence pattern. In a multivariate analysis, lymph node spread was the only variable (including the tested biomarkers) associated with pattern of failure. Patients without regional lymph node metastases had an increased risk of a local-only recurrence, typically in a relatively delayed fashion.¹⁶⁰ These data highlight that some patients would likely benefit from intensified local therapy, whereas others are best suited to receive systemic therapy only. Future studies are needed to define a personalized approach.

Adjuvant Therapy

According to the National Comprehensive Cancer Network (NCCN) guidelines, adjuvant chemotherapy is recommended for patients who recover well from pancreatic resection. Acceptable strategies include chemotherapy alone (gemcitabine, 5-FU, or capecitabine monotherapy), or chemoradiation plus chemotherapy (gemcitabine or 5-FU monotherapy, either given before or after chemoradiation).¹⁵⁷ Unfortunately, these regimens all consist of single-agent therapy with minimally effective agents. A meta-analysis of five randomized adjuvant trials including 951 patients concluded that adjuvant therapy provides a 3-month median survival advantage, and a 3% absolute improvement in 5-year survival. To put these findings in perspective, patients typically require a 6-month course of adjuvant treatment to achieve a 3-month survival.¹⁵⁸ Although these figures may appear unappealing to many patients, the reality is more complex; many patients receive no benefit at all, and may even be harmed with treatment, whereas a subset of patients receive a robust and durable survival benefit with these adjuvant treatments. Identifying which patients are most likely to experience a survival benefit is as important as discovering superior treatment regimens.

Adjuvant Trials

There have been eight prospective and randomized adjuvant trials that have shaped current treatment recommendations, including: five European trials, two in the United States, and one in Japan (Table 49.5).¹⁶³⁻¹⁷⁰ Out of these eight trials, only four were considered positive with respect to the planned primary end point (one in the United States and three in Europe).^{164,165,168,169} The continent where these trials were performed has played an important factor in defining the standard of care adjuvant treatment strategy around the world; chemoradiation is commonly performed in addition to chemotherapy in the United States, whereas chemotherapy

(without radiation) is the standard in Europe. The principal adjuvant trials will briefly be reviewed, emphasizing the strengths and weaknesses of the studies.

The Gastrointestinal Tumor Study Group (GITSG) trial was the first of the adjuvant trials and was a small phase III trial (by today's standards, $n = 49$ patients treated between 1974 and 1982) performed in the United States. Patients in the experimental arm received 40 Gy (split course with 20 Gy in each course, and a 2-week break in the middle). Bolus 5-FU was administered weekly for 2 years as maintenance therapy (500 mg/m^2), but was given daily for the first 3 days of each radiation course. The treatment arm was compared to an observation only arm, and the chemoradiation group had superior survival (20 versus 11 months; $p = 0.04$). The study has been criticized for its small sample size. Furthermore, it is not known whether the observed benefit was attributable to chemoradiation, to maintenance chemotherapy, or to both. Nevertheless, this landmark study established a role for adjuvant chemoradiation as an acceptable treatment for resected PDA in the United States.

Two small trials (in Norway¹⁶⁹ and Japan¹⁶⁷) were performed over the last 15 years that provided equivocal results for chemotherapy alone, compared to surgery only. In the Norwegian trial, authored by Bakkevoid et al.,¹⁶⁹ 61 patients with periampullary cancer (only 47 with PDA) were randomized to receive doxorubicin, mitomycin C, and 5-FU (six cycles), or observation. Patients receiving adjuvant chemotherapy had an improved median survival (23 versus 11 months; $p = 0.04$), but 2-year survival was similar (43% versus 32%; $p = 0.1$). In the Japanese trial, 89 patients were randomized to just two cycles (separated by 4 to 8 weeks) of 5-FU (500 mg/m^2 as a continuous infusion over 5 days) plus cisplatin (80 mg/m^2 on day 1 of each cycle), versus observation. OS was similar in the two groups (12.5 versus 15.8, respectively; $p = 0.9$).

The European Organization for Research and Treatment of Cancer (EORTC) trial was Europe's response to the GITSG trial and proved to be the largest adjuvant trial for PDA at that time.¹⁶³ A total of 218 patients with either PDA or other periampullary cancer were randomized to chemoradiation or observation. The treatment arm received split-course radiation for 40 Gy (as with GITSG). However, 5-FU was given as a continuous infusion (as opposed to bolus) on days 1 through 5 of each radiation course (for a total of 125 mg/m^2). No maintenance chemotherapy was administered. OS was 21.6 months with treatment and 19.2 months with observation ($p = 0.5$).

The European Study Group for Pancreatic Cancer (ESPAC-1) was the next large randomized adjuvant trial.¹⁶⁵ A total of 289 patients were randomized to a 2×2 design, with one of the four groups receiving no treatment. Treatment groups included (1) chemoradiation (40 Gy split-course radiation with bolus 5-FU at 500 mg/m^2 on days 1 through 3 of radiation, as with GITSG)

followed by chemotherapy (bolus leucovorin at 20 mg/m^2 and 5-FU at 425 mg/m^2 daily for 5 days, every 28 days for six cycles); (2) adjuvant chemotherapy only (without chemoradiation) as previously defined for group 1; (3) chemoradiation only (without chemotherapy) as previously defined for group 1; and (4) no treatment. The two groups receiving chemotherapy (groups 1 and 2) had superior survival as compared to those who did not (20.1 versus 15.5 months; $p = 0.009$). When chemoradiation was analyzed separately, the OS were 15.9 months with the two chemoradiation groups (groups 1 and 3) and 17.9 months without chemoradiation (groups 2 and 4; $p = 0.05$). When patients who received chemotherapy only were excluded from the no chemoradiation group (leaving just patients in the observation group), there was still a strong trend toward improved survival without chemoradiation. The results have been widely questioned because of the complex study design and because patients apparently received suboptimal radiation therapy (split course, no central quality of radiation control, 9% protocol violation, a very high [62%] local failure rate compared to recent trials). Although this study established chemotherapy alone as an acceptable standard of care in Europe and other parts of the world, oncologists in North America remain largely divided on the role of chemoradiation.

The Charité Onkologie (CONKO-001) trial primarily took place in German centers between 1998 and 2004,¹⁵⁹ with updated results recently reported.¹⁶⁴ The trial was an appropriate follow-up to ESPAC-1, which was interpreted in Europe as evidence in favor of adjuvant chemotherapy (without chemoradiation). Moreover, only 5-FU-based adjuvant chemotherapy had been tested up to that point, whereas the superiority of gemcitabine over 5-FU had been established for patients with advanced PDA (discussed in the Stage IV: Metastatic Disease section).¹⁷¹ A total of 368 patients were randomized to receive six cycles of gemcitabine (4-week cycles) at a weekly dose of $1,000 \text{ mg/m}^2$ every 3 weeks with a 1 week break versus observation alone. Chemoradiation was not included in the treatment arm. The initial report reached its primary end point of disease-free survival (13.4 versus 6.9 months; $p < 0.001$), but OS was not significantly different.¹⁵⁹ However, the updated analysis demonstrated improved OS with gemcitabine (22.8 versus 20.2 months; $p = 0.01$).¹⁶⁴ The small absolute difference in survival could be explained, in part, by the fact that 38% of patients did not receive the planned dose of gemcitabine and 13% did not receive at least one full cycle. In addition, most patients in the control arm received palliative chemotherapy once a recurrence was detected. Grade 3 through 4 toxicities were extremely rare in the treatment arm (no specific toxicity occurred in more than 3% of patients in the gemcitabine group). Although the median survival advantage is modest, it should be emphasized that the 5-year survival advantage was 10% (20.7% versus 10.2%; $p < 0.05$) and the 10-year survival advantage was 5% (12.2% versus 7.7%).

Figure 49.6 Improved long-term survival with gemcitabine monotherapy, in the CONKO-001 trial. The highlighted area represents patients who likely had a substantial benefit from gemcitabine monotherapy. (Modified from Oettle H, Neuhaus P, Hochhaus A, et al. Adjuvant chemotherapy with gemcitabine and long-term outcomes among patients with resected pancreatic cancer: the CONKO-001 randomized trial. *JAMA* 2013;310:1473–1481.)

These data provide very strong evidence that, in a small subset of patients (i.e., 1 in 10), gemcitabine monotherapy is highly effective (Fig. 49.6). The opportunity to achieve long-term survival due to gemcitabine (albeit uncommon) is an important consideration for patients contemplating adjuvant treatment, despite the meager improvement in median survival.

The European ESPAC-3 trial is the largest adjuvant trial to date, and directly compared chemotherapy with gemcitabine (1,000 mg/m² over 30 minutes weekly, 3 out of 4 weeks) versus 5-FU (bolus folinic acid at 20 mg/m² plus bolus 5-FU at 425 mg/m² on days 1 to 5, every 28 days for six cycles as administered in ESPAC-1). As with CONKO-001, no adjuvant chemoradiation was given. Median OS were 23.6 and 23.0 months, respectively ($p = 0.4$), demonstrating equivalence between the two agents. However, this study did not change the emerging paradigm of frontline gemcitabine monotherapy at most centers, because toxicity was less with gemcitabine (14% serious adverse events with 5-FU versus 7.5% with gemcitabine; $p < 0.001$). The increased toxicity due to 5-FU was primarily related to increased stomatitis and diarrhea.

Finally, RTOG 9704 was the second United States adjuvant trial, completed in 2002¹⁷² and updated in 2011.¹⁷⁰ The trial's treatment arms paralleled the ESPAC-3 study (5-FU versus gemcitabine), except patients in both treatment groups received 5-FU-based chemoradiation in the middle of their adjuvant chemotherapy course. Total treatment duration in both groups was 6 months, and the study question related to chemotherapy (5-FU versus gemcitabine), and not the role of chemoradiation. A total of 451 patients were randomized to chemotherapy with 5-FU at 250 mg/m² per day given as a continuous infusion (different from ESPAC-3) or gemcitabine 1,000 mg/m² given weekly. Patients received one chemotherapy cycle prior to chemoradiation (3 weeks) and 12 additional weeks afterwards (two cycles of 5-FU consisting of 4 weeks on and 2 weeks off; three cycles of gemcitabine with 3 weeks on and 1 week off). Chemoradiation was given to all study patients as 50.4 Gy with continuous infusion 5-FU (250 mg/m² per day), and prospective quality assurance was performed. The primary end points of the study were OS for the whole cohort and for pancreatic head cancers. For all patients, OS was similar in the gemcitabine and 5-FU arms (18.5 versus 16.4 months; $p = 0.5$). In patients with pancreatic head tumors (86% of the total study population), those receiving gemcitabine had a trend toward superior survival in the multivariate analysis (20.5 versus 17.1 months; $p = 0.08$). The site of first relapse was recorded in this study, and was distant in roughly

70% of patients, and local-regional in 30% (a low figure relative to the local recurrence rate reported in ESPAC-1). Subsequent sites of recurrence were not reported. The RTOG-9704 study had several additional informative findings. Patients treated at centers that did not meet the quality assurance standards had inferior outcomes.¹⁷³ As previously described, postoperative CA 19-9 was identified as an important prognostic variable and should be considered in planning future adjuvant trials.¹⁵⁴ Finally, the inferior outcomes in patients with PDA of the left side of the pancreas raises questions about whether this group should be included in adjuvant trials with chemoradiation.

Future Questions and Ongoing Adjuvant Trials

Based on these trials, 6 months of adjuvant therapy is clearly supported as the standard of care for patients with resected PDA. Whether adjuvant chemoradiation is important remains an unanswered question, and is the subject of an ongoing randomized trial in the United States (RTOG 0848, NCT01013649). The study compares the impact of chemotherapy alone to chemotherapy plus chemoradiation. Patients in the radiation arm will receive 28 fractions of 1.8 Gy (50.4 Gy total, either 3-D conformal or intensity-modulated radiotherapy) and either capecitabine (825 mg/m² twice daily) or 5-FU (250 mg/m² per day as a continuous infusion for the duration of radiation) as a radiosensitizer. Unlike the RTOG 9704 trial, chemoradiation is administered after five cycles of gemcitabine-based chemotherapy have been completed. This trial design reflects an emerging trend in many centers toward deferring chemoradiation until after chemotherapy is completed in order to maximize systemic control early on and to spare patients who recur early at distant sites the cost and morbidity of radiation. The next ESPAC trial (ESPAC-4, ISRCTN96397434) is evaluating the role of doublet therapy (gemcitabine plus capecitabine versus gemcitabine alone) in the adjuvant setting. It is worth pointing out that this regimen did not improve OS in advanced pancreatic cancer (see the Stage IV: Metastatic Disease section).¹⁷⁴ CONKO-005 (DRKS00000247) is testing the addition of erlotinib to the standard-of-care gemcitabine (versus gemcitabine alone) based on a small, but statistically significant improvement in survival in the metastatic setting.^{175,176} As discussed later in detail, two regimens, (1) gemcitabine plus nab-paclitaxel and (2) FOLFIRINOX, were recently shown to be superior to gemcitabine in the metastatic setting.^{177,178} In light of these encouraging results, there are plans to test both regimens in the adjuvant setting (NCT01964430 and NCT01526135, respectively), using a similar control arm in both studies (gemcitabine monotherapy). Finally, the role of neoadjuvant chemotherapy in patients with resectable disease is not known. There are selected centers that routinely treat patients with resectable disease with neoadjuvant therapy,⁸⁴ and the NCCN guidelines recommend that such an approach be conducted as part of a clinical trial. In one of the largest series, from the M.D. Anderson Cancer Center,⁸⁴ outcomes are favorable (34 months) for patients who ultimately make it to pancreatic resection. The median survival of the entire cohort (22.7 months) in an intent-to-treat analysis is similar to historical controls with localized disease (see Table 49.5). Proponents argue that a neoadjuvant approach allows for an objective assessment of treatment response, early treatment of microscopic metastases, and an additional 3 to 6 months to monitor disease biology before committing to an operation with substantial risk. It is likely that as adjuvant treatment improves, more centers will move to a neoadjuvant paradigm, similar to the treatment of other upper gastrointestinal cancers.

Surveillance Postresection

The current NCCN guidelines recommend that patient follow-up after resection should include visits every 3 to 6 months for 2 years, and then annually. Surveillance CT scans and serial tumor markers (CA 19-9 at minimum) should be assessed, along with a history and physical exam. These recommendations are not based

on Level 1 evidence, but rather expert consensus.¹⁷⁹ In practice, surveillance patterns range widely from close follow-up with CT imaging and CA 19-9 levels every 3 months, to no routine surveillance at all.¹⁸⁰ Poor outcomes after recurrence (roughly 6 to 12 months in the adjuvant trials discussed previously), and a lack of proven benefit for salvage chemotherapy, argue against close surveillance. However, as the number of second-line agents with activity against PDA increases, so will the opportunity to prolong survival with early detection of recurrence and intervention. It should be noted that a rise in CA 19-9 often precedes radiographic evidence of recurrence by 3 to 12 months.¹⁸¹ However, initiating chemotherapy based on changes in tumor marker levels alone is not currently recommended (although widely practiced), due to the risk of false positive and false negative results.^{153,154}

There are a few reports that support the benefit of close surveillance and early intervention. One study, presented in abstract form, described 139 patients who underwent resection for PDA. All patients were advised to have CT scan and CA 19-9 surveillance every 3 months in the first year, every 6 months in the 2nd year, and annually thereafter. The patients were retrospectively analyzed in three groups: those who followed the recommendations, those who underwent surveillance but with less frequency than recommended, and those who did not follow up. Survivals in the three groups were 16.6, 15.7, and 8.7 months, respectively. The authors concluded that close follow-up is advisable. Notably, the proportions of patients who received adjuvant treatment in each group were not reported.

Selected patients may even benefit from a metastasectomy. Pulmonary metastases (as compared to liver or peritoneal metastases) typically occur in a delayed fashion after surgery.¹⁶⁰ Therefore, the biology and natural history of patients who develop isolated pulmonary metastases may represent a unique subgroup where resection of these lesions is beneficial. The Johns Hopkins group identified 31 patients with isolated lung metastases at a median of 34 months post pancreatectomy. A total of 9 had the lung lesion resected, and these patients survived an additional 19 months (range 5 to 29 months) after the intervention.¹⁸²

STAGE III: LOCALLY ADVANCED DISEASE

AJCC Staging Versus “Intent of Management”-Based Staging

In the current (7th) edition of AJCC staging for pancreatic adenocarcinoma, stage III cancers are T₄, N_{any} M₀ malignancies, with T₄

defined as a “tumor [that] involves the celiac axis or the superior mesenteric artery (unresectable primary tumor).” A representative CT scan of stage III PDA is provided in Figure 49.7. These presentations account for about 30% of all pancreatic cancers and typically have an average survival of 1 year or less, even when treated (see Table 49.1). However, it is problematic to lump these patients into a single group with regard to treatment decisions, because of heterogeneous biology and differences in other relevant clinical factors. Management decisions for patients with locally advanced tumors are based on both the local extent of involvement of the celiac and/or SMA arteries and critical primary branches, such as the proper hepatic artery, as well as the clinician’s answer to the following questions:

1. What therapeutic goal appears to be most rational based not only on the tumor staging, but also on performance status, weight loss, and significant comorbid illnesses? Along these lines, is the treatment potentially curative? Is minimal or moderate antineoplastic intensity more appropriate? Or is treatment supportive and purely palliative?
2. What is the level of treatment intensity that this patient would be able to accept and withstand psychologically and emotionally in addition to physiologically?
3. What are the support structures surrounding this patient, and are they up to the challenges that will be incurred by the management selected?

Pragmatically, stage III clinical presentations have been divided into *borderline resectable* and *clearly unresectable* (introduced previously in the section Stage I, II: Localized Disease, Evaluation and Assessing Resectability), with the conceptual distinction being the probability of safely and successfully resecting the tumor without antecedent chemotherapy or chemoradiotherapy.

Basic Management Considerations

The initial evaluation of patients with presumed pancreatic adenocarcinoma will be the same whether the patient ultimately is demonstrated to have a resectable, borderline resectable, or locally unresectable disease at presentation. This component of management has been addressed previously in the chapter (see Stage I, II: Localized Disease, Presentation and Evaluation and Assessing Resectability). For patients treated initially with chemotherapy or chemoradiation, several additional management considerations need to be considered (also relevant for patients with resectable disease who are to receive neoadjuvant treatment).

Figure 49.7 CT scans of a locally advanced, stage III PDA in the pancreatic body. Coronal images. **(A)** The arterial phase. Visceral arteries named are left gastric artery (LGA), common hepatic artery (CHA), and superior mesenteric artery (SMA). The CHA is encased. **(B)** The venous phase. The portal splenic confluence is completely occluded.

Patients generally require histologic confirmation of a pancreatic cancer diagnosis prior to treatment. Additionally, relief of obstructive jaundice and duodenal obstruction is necessary when present. These interventions will be concurrent with other basic assessments and interventions such as nutritional optimization, treatment of dehydration and electrolyte abnormalities, pain management, and attention to depression if present. It is important to emphasize that multidisciplinary teams with focused, management experience for gastrointestinal (GI) malignancies of the upper abdomen achieve the best results, and include expertise in pathology, chemotherapeutic, radiotherapeutics, surgical management, interventional radiology, and endoscopy, as mentioned in the opening of the chapter.¹⁸⁵

Local–Regional Unresectable Disease

Impact of Prognostic Factors in the Management of Locally Unresectable Patients

Patients with locally advanced, or stage III, PDA have an average OS between 7 and 12 months (Table 49.6). Several patient-specific factors have been adversely associated with outcome in this context, including anemia, poor performance status, elevated CA 19-9, and elevated Charlson Comorbidity Score. In addition, use and response to systemic chemotherapy as the initial treatment, prior to chemoradiotherapy, appears to favorably predict (and possibly impact) survival.^{184–187}

Evolution of Management for Local–Regional Unresectable Disease

The early, practice defining, randomized experiences have been reviewed in many prior publications and textbooks,¹⁸⁸ and key ones are highlighted in Table 49.6. It is important to remember how dated some studies are with respect to patient selection and evaluation, chemotherapy selection, and radiation planning and delivery (typically delivered as 2-D nonconformal, split course, low-dose therapy). Nevertheless, these papers established proof of principle for treatment feasibility with acceptable toxicity, and the value of 5-FU–based radiosensitization in this context.

From the mid 1990s through the first decade of the current century, there have been a series of important lessons learned in the management of locally advanced pancreatic cancer. Acceptable chemoradiation strategies integrating insights gained from past studies are summarized in Table 49.7. There is a biologic basis for needing both improved local control and improved systemic control to optimize results.

Improved local control in pancreatic cancer has been strongly suggested by the autopsy studies by Iacobuzio-Donahue et al.,⁴⁹ previously described (see the Stage I, II: Localized Disease, Adjuvant Therapy section), and validated in patients with locally advanced disease.¹⁶¹ Investigators observed that patients with tumors having intact SMAD4 expression were more likely to have locally destructive tumors and a lower burden of metastatic disease than patients with tumors showing SMAD4 loss. Recently, Oshima et al.¹⁸⁹ found that abnormal TP53 expression (either absence or

TABLE 49.7

Recommended Radiation Treatment Volumes in Commonly Used Chemoradiation Regimens for Localized Pancreatic Cancer

Chemotherapy Choice	Chemotherapy Dose and Schedule	Radiation Dose and Schedule	No Arterial Involvement or Abutment with Likely Resectability (T3 or T4)	Extensive Arterial Involvement with Uncertain Resectability or Arterial Encasement/Unresectable (T4)
Gemcitabine	400–500 mg/m ² weekly	50.4 Gy over 5.5 wks (good PS) or 30 Gy over 2 wks (poor PS)	GTV only	GTV only
	1 g/m ² weekly	36 Gy over 3 wks	GTV only	GTV only
	40 mg/m ² twice weekly	50.4 Gy over 5.5 wks	GTV + ENI	GTV only
Capecitabine	800–825 mg/m ² twice per day on days of radiation	50.4 Gy over 5.5 wks (good PS) or 30 Gy over 2 wks (poor PS)	GTV + ENI	GTV only
PVI 5-FU	225 mg/m ² daily or 300 mg/m ² on days of radiation	50.4 Gy over 5.5 wks (good PS) or 30 Gy over 2 wks (poor PS)	GTV + ENI	GTV only

PS, performance status; GTV, gross tumor volume; ENI, elective nodal irradiation; PVI, protracted venous infusion.

Modified from Royal RE, Wolfe RA, Crane CH. Cancer of the pancreas. In: DeVita VT Jr, Lawrence TS, Rosenberg SA, eds. *DeVita, Hellman, and Rosenberg's Cancer: Principles & Practice of Oncology*. 9th ed. Philadelphia: Lippincott Williams & Wilkins; 2011.

nuclear accumulation) was associated with a local–regional recurrence pattern in patients with resected PDA, whereas CDKN2A loss was associated with widespread metastases.¹⁸⁹ Similar to an aforementioned study by Winter et al.,¹⁶⁰ SMAD4 expression was not associated with pattern of failure in this patient cohort following resection.¹⁸⁹

Past studies suggest that the controversy of using chemotherapy alone versus chemoradiotherapy should be reframed to acknowledge that there might be potential roles of each. There have been several randomized trials comparing chemotherapy to chemotherapy plus chemoradiation,^{190–193} with mixed results (each appear in Table 49.6). An older ECOG study published in 1985 (with the aforementioned limitations) compared weekly 5-FU against the same chemotherapy treatment preceded by 40 Gy radiation (combined with 5-FU) and found no difference in survival. The multi-institution French Fédération Francophone de Cancérologie Digestive-Société Française de Radiothérapie Oncologie (FFCD/SFRO) study found decreased survival in patients receiving 60 Gy radiation concomitantly with 5-FU and cisplatin, and followed with maintenance gemcitabine, compared to gemcitabine alone (8.6 versus 13 months). The chemoradiation regimen used in this trial has been criticized as being particularly toxic (more on this in the following).¹⁹¹ The LAP-07 trial with gemcitabine or gemcitabine plus erlotinib for four cycles, followed by either chemoradiotherapy or additional chemotherapy (two cycles), failed to show any difference in survival between the two arms. About one-third of patients had progressed by the time of the second randomization. The trial results, although final, have only been reported in abstract form.¹⁹⁴ However, a GITSG study from 1988 comparing 5-FU and radiation followed by streptozotocin, mitomycin C, and 5-FU chemotherapy to the same chemotherapy alone showed an improved median survival (9.7 versus 7.4 months) with multimodality therapy.¹⁹⁰ Most recently, ECOG 4201 from 2011 suggested that locally advanced patients randomly assigned to receive chemoradiotherapy with gemcitabine followed by five cycles of gemcitabine alone did better than patients receiving gemcitabine without radiotherapy (11.1 versus 9.2 months; $p = 0.016$).¹⁹³ It is noted that this trial was closed, with only 71 patients accrued and analyzed, a potential criticism of the results. Other nonrandomized studies suggesting benefit to using a combination of modalities, rather than one modality, include the recently reported Massachusetts General Hospital experience (improved survival with chemotherapy plus chemoradiation versus chemoradiation alone, HR = 0.46; $p < 0.001$),¹⁸⁴ and a German study in which treatment decisions were assigned from tumor board discussions

(chemoradiotherapy plus chemoradiation, median survival 13.0 months versus 8.0 months without additional chemotherapy).¹⁹⁵ On further analysis, the authors could not find prognostic factor variation between the two groups to explain this difference.

Gemcitabine has been found to be marginally superior to 5-FU in the metastatic setting.¹⁷¹ The drug also has marginal efficacy as a single-agent adjuvant therapy after resection for PDA.¹⁶⁴ There is some suggestion that it may be better than 5-FU in the adjuvant setting, when chemoradiation is included,¹⁷⁰ although there is no such trend in a European trial comparing these agents without chemoradiation.^{166,170} Thus, there has been interest in exploring gemcitabine as a radiation sensitizer; indeed, the drug is potent in this role based on preclinical and clinical data.¹⁹⁶ Investigators from the M.D. Anderson Cancer Center, the University of Michigan, and other sites explored the use of gemcitabine with radiotherapy in various contexts, with the following observations: Radiotherapy fields designed to cover gross tumor and at risk nodal basins cannot safely be targeted with concurrent gemcitabine unless the gemcitabine dose is reduced from the chemotherapy-only level of 1,000 mg/m² to 300 to 600 mg/m². Additionally, the daily fraction size should not exceed 1.8 Gy when targeting expanded fields with draining lymph nodes. If the desire is to administer full-dose gemcitabine (1,000 mg/m²) weekly with higher radiation doses (e.g., 2.4 Gy fractions), then radiotherapy must be limited to gross tumor only with tight margins, and special attention must be given toward inadvertent targeting organs such as the duodenum, stomach, and small bowel. Subsequent studies have demonstrated that respecting these guidelines allows for acceptable toxicity, especially when combined with appropriate supportive care measures, treatment planning that accounts for target and organ movement with respiration, and intensity modulated planning and delivery aimed at minimizing doses to sensitive critical organs.^{196–200}

The work of Ben Joseph et al.¹⁹⁷ at the University of Michigan validates this approach. Investigators conducted a phase I/II dose escalating study of radiotherapy dose over 25 fractions (totaling 50 to 60 Gy) in 50 patients, all deemed to have locally advanced PDA (not borderline resectable). The maximal tolerated dose was 55 Gy (2.2 Gy per fraction) in combination with fixed-dose rate gemcitabine (1,000 mg/m²). Patients had a median survival of 14.8 months and 24% (12 of 50 patients, a very high rate compared to previous studies^{161,191,201,202}) underwent resection (10 R₀ and 2 R₁). Among resected patients, the median survival was 32 months. A meta-analysis of three randomized trials and one comparative retrospective study (including 229 patients) revealed a small but significant survival advantage with gemcitabine-based chemoradiation

(at 12 months: HR, 1.5; $p = 0.03$), over 5-FU–based treatment, although toxicity was higher.²⁰³

Technologic advances combined with greater understanding of the mechanisms and impact of acute radiation toxicity have improved the safety profile of treatment. Excessive acute toxicity quickly results when the radiation fractional dose increases, the total dose increases, the field sizes are too large for the degree of drug sensitization or intensity, or radiation is delivered without careful consideration of limiting dose volume to the stomach, duodenum, small bowel, or other critical organs. There is increasing consensus that such toxicity can be associated with symptoms, increased costs, and decreased survival.^{191,200}

Capecitabine is an appealing alternative to 5-FU or gemcitabine as a radiosensitizer. Capecitabine is a prodrug of 5-FU with near-complete oral bioavailability. It is converted to its active form through a three-step process, with the last step occurring more reliably within tumor cells than in nonmalignant cells, due to higher thymidine phosphorylase levels. Thus, systemic levels of active 5-FU are actually decreased with capecitabine, theoretically widening the therapeutic window of the drug. Aside from hand-foot syndrome associated with capecitabine, clinical trials reproducibly demonstrate an improved safety profile. The efficacy of capecitabine is comparable to 5-FU, at least in studies of other cancer types that directly compare them.²⁰⁴ Importantly, oral dosing obviates the need for semipermanent venous access and the attendant risks of thrombosis and infection. Nonrandomized data demonstrate that capecitabine (typically administered at a daily dose of around 1,600 mg/m²) has comparable efficacy to continuous infusion 5-FU, and an improved toxicity profile, as a radiosensitizer in patients with locally advanced PDA receiving intensity-modulated radiation therapy (IMRT).^{205,206} Finally, the recently published SCALOP I randomized trial in patients with locally advanced PDA, has suggested mildly increased efficacy (OS 15.2 versus 13.4 months; $p = 0.01$) and decreased toxicity of capecitabine with irradiation, as compared to gemcitabine. In this study, sensitized radiation was administered after four cycles of gemcitabine and capecitabine chemotherapy (randomization was performed after three cycles).²⁰⁷ Note that the chemosensitizing dose of gemcitabine (300 mg/m²) was lower than the fixed-dose rate levels successfully used in the abovementioned Ben Josef study.¹⁹⁷

A final lesson from previous studies of chemoradiation for locally advanced pancreatic adenocarcinoma demonstrate that induction chemotherapy prior to chemoradiation has advantages. Nevertheless, chemotherapy, chemoradiation, or both have been studied and are acceptable approaches for locally advanced PDA. There are no level 1 data conclusively supporting one approach over the other. However, several studies provide a meaningful rationale for beginning with induction chemotherapy. Roughly two-thirds of patients with locally advanced PDA develop systemic metastases during treatment. Some of these individuals are less likely to benefit from radiation, and the costs and side effects of local radiation therapy may be avoided.²⁰⁸ An ad hoc analysis of a prospective, nonrandomized study (GERCOR), revealed that patients with locally advanced PDA who received consolidation chemoradiation after induction chemotherapy had improved survival, as compared to those who had chemotherapy alone (15.0 versus 11.7 months; $p < 0.001$).²⁰⁸ This has been validated by other retrospective data.²⁰⁹ The SCALOP trial, as previously described, showed that sequenced chemoradiation after chemotherapy achieves very good results with locally advanced PDA.²⁰⁷ The GERCOR LAP-07, described previously, warrants additional mention here, because no benefit was observed with chemoradiation (50.4 Gy plus capecitabine) after chemotherapy (gemcitabine plus erlotinib of gemcitabine alone), as compared to additional chemotherapy ($n = 269$; OS, 15.2 versus 16.4 months; $p = 0.8$).¹⁹⁴

Along these lines, certain multidrug combinations with higher response rates for advanced PDA than gemcitabine monotherapy (see the Stage IV: Metastatic Disease section) are also promising regimens for locally advanced PDA. FOLFIRINOX (5-FU, oxaliplatin,

leucovorin, and irinotecan) has a response rate of 27% in the locally advanced setting,²¹⁰ which rivals the best results with multimodality therapy.^{197,207} Planned and ongoing trials with FOLFIRINOX, as well as with nab-paclitaxel plus gemcitabine (with or without radiation), will help establish the role of these treatments for locally advanced PDA.

Management of Borderline Resectable Patients

Current NCCN guidelines for borderline resectable patients favor neoadjuvant therapy over directly going to surgery, while acknowledging the validity of both approaches and the absence of phase III data to definitively answer the issue.¹⁵⁷ A meta-analysis of 182 patients from 10 prospective trials of borderline resectable patients included seven studies reporting on the impact of chemoradiation (with or without chemotherapy) and three on chemotherapy alone.²¹¹ At restaging following neoadjuvant therapy, 16% of patients responded to treatment, 69% had stable disease, and 19% showed progression. The median survival for the cohort was 22.0 months, and treatment-related grade 3 to 4 toxicity was observed in 32% of patients. Surgical exploration was performed in 69% of patients, and 80% of surgically explored patients were resected. Moreover, 83% of resected specimens had microscopically negative resection margins. Among resected patients, 61% were alive at 1 year, and 44% were alive at 2 years. The median survival in this highly selected and favorable group was 22.0 months.

Although the survival of patients with borderline PDA after neoadjuvant treatment and resection is comparable to patients with resectable PDA,²⁷ these data should be interpreted with a few points of caution. First, the study was underpowered and not designed to determine the best neoadjuvant regimen; thus, treatment choice is largely dependent on institutional preferences. Second, resected patients represent 56% of the total cohort, and are enriched for patients with tumors that have favorable biology. In these nonrandomized studies, it is possible that intrinsic biologic factors were more important determinants of survival than neoadjuvant treatment. Notably, nonresected patients with borderline PDA have a survival around 1 year, which is similar to patients with locally advanced disease.²¹² Finally, roughly 40% of patients with potentially resectable tumors do not undergo resection when a neoadjuvant approach is used. Whether unresected patients suffered a missed opportunity for resection (and therefore for long-term survival) or were spared ineffective surgery is unknown. Most likely, the answer lies somewhere in the middle.

EMERGING ROLE OF STEREOTACTIC BODY RADIOTHERAPY

SBRT is hypofractionated (one to five fractions) radiotherapy given in doses that, in aggregate, do not exceed 50 to 60 Gy per course. Single fraction courses are usually in the dose range of 20 to 25 Gy. The number of fractions and dose per fraction is determined by tumor size and radiation tolerance of the involved and/or adjacent organs. To be safe, these large-dose fractions are given with extra attention to immobilization, controlling for respiratory movement, image guidance, and dose shaping around critical structures. The risk of severe or lethal normal organ damage is substantial in the absence of proper attention to all required, relevant considerations. In pancreatic applications, the primary dose-limiting structure is the duodenum, followed by the stomach, remaining small bowel, and other adjacent organs/structures. This approach has been applied with and without chemotherapy in a variety of pancreatic contexts, including locally unresectable, borderline resectable, locally recurrent, and as an adjuvant management boost after conventional radiotherapy.^{213–215} These studies demonstrated feasibility and acceptable toxicity in experienced hands, although the exact role of this modality remains to be defined.

STAGE IV: METASTATIC DISEASE

Approximately 50% of patients with PDA will be diagnosed with distant metastatic (stage IV) disease at the time of presentation.¹ Prognosis is dismal, with a median OS of less than 6 months and an estimated 2-year survival of only 2%.^{3,7} Chemotherapy in this setting improves survival by just a few additional months. Therefore, the goals of therapy in this patient population are to prolong survival, as well as to palliate symptoms.

Gemcitabine as a Gold-Standard Therapy for Metastatic Pancreatic Adenocarcinoma

5-FU was the principal treatment option for metastatic pancreatic cancer through the 1990s, although response rates were under 20% and median survival was just 6 months.²¹⁶ Other agents or combinations of drugs failed to show any improvement over 5-FU monotherapy until a landmark study in 1997 by Burris et al.¹⁷¹ demonstrating the superiority of gemcitabine for advanced PDA. Since that study, gemcitabine has become the single most important pancreatic cancer therapy, and the standard treatment arm in at least 19 phase III studies (Table 49.8).

Gemcitabine (difluorodeoxycytidine [dFdC]) is a nucleoside analog of deoxycytidine, and it is administered as a prodrug. Upon entry into the cell, gemcitabine is phosphorylated by deoxycytidine kinase (DCK) to a monophosphate form (dFdCMP). Similar to the association between thymidine phosphorylase and the prodrug capecitabine, elevated DCK levels in tumor cells (compared to normal tissues)²¹⁷ enhance the therapeutic window of gemcitabine. dFdCMP is then phosphorylated into active diphosphate (dFdCDP) and triphosphate (dFdCTP) forms. The active metabolites incorporate into DNA and inhibit chain elongation. Moreover, they deplete nucleotide pools by competitively inhibiting ribonucleotide reductase.²¹⁸

In the 1997 Burris trial, 126 patients with advanced pancreas cancer were randomized to either of two arms: (1) gemcitabine 1,000 mg/m² weekly for 7 weeks followed by 1 week of rest, then 3 doses per week every 4 weeks thereafter, or (2) bolus 5-FU 600 mg/m² once per week.¹⁷¹ Patients primarily had metastatic disease, although 26% had locally advanced disease. Treatment in both arms was generally well tolerated. Grade 3 through 4 hematologic toxicities were higher with gemcitabine, including neutropenia (25.9% versus 4.9%), thrombocytopenia (9.7% versus 0%) and anemia (9.7% versus 0%). Grade 3 through 4 nausea was also more frequent in the gemcitabine arm (9.5% versus 4.8%). Clinical benefit, based on pain score, performance status, and weight, was noted in 23.8% of patients in the gemcitabine arm versus only 4.8% in the 5-FU arm ($p = 0.0022$). The survival advantage with gemcitabine was just over 5 weeks, with median OS of 5.65 and 4.41 months, respectively ($p = 0.0025$). Survival at 12 months was 18% in the gemcitabine arm versus 2% in the 5-FU arm. Partial tumor responses were observed in 5% of patients in the gemcitabine group, and stable disease was observed in 39%. In contrast, no partial tumor responses were observed with 5-FU, and only 19% of patients experienced stable disease. As a result, gemcitabine was approved by the U.S. Food and Drug Administration (FDA) in 1997 for first-line treatment for locally advanced unresectable or metastatic pancreas cancer.

Two studies have focused on modifying the dosing and infusion rates of gemcitabine in order to increase the concentration of intracellular, activated gemcitabine. Tempero et al.²¹⁹ compared two

different dose-intense regimens (compared to the Burris regimen) in a randomized phase II study. A total of 92 patients were randomized to either *standard* 30 minute infusion at a dose of 2,200 mg/m² versus 1,500 mg/m² over 150 minutes at a fixed-dose rate (FDR) of 10 mg/m² per minute.²¹⁹ All patients had locally advanced (8%) or metastatic pancreatic cancer (92%). Although there was no difference in the primary end point (i.e., time to treatment failure), patients in the standard arm had a median OS of 5 months, whereas those in the FDR had a median survival of 8 months ($p = 0.013$). Pharmacokinetic analyses showed a twofold increase in the intracellular (peripheral mononuclear cells) concentration of gemcitabine triphosphate with FDR gemcitabine, even though the total dose given was 30% less. Consistent with these data, grade 3 to 4 hematologic toxicity was also greater with FDR gemcitabine. Subsequently, the Eastern Cooperative Oncology Group (ECOG) conducted a three-arm phase III study (E6201) comparing gemcitabine (1,000 mg/m²) plus oxaliplatin (100 mg/m²) every 2 weeks versus a weekly 30-minute infusion of gemcitabine (1,000 mg/m²) versus weekly FDR gemcitabine (1,500 mg/m² as previous).²²⁰ A total of 832 patients were enrolled. The study confirmed an increase in OS for the FDR arm compared to the 30-minute infusion of gemcitabine arm (6.2 months versus 4.9 months; $p = 0.04$). However, the OS benefit actually did not meet the prespecified criteria for significance (a 33% decrease in survival). In addition, patients experienced greater toxicities with grade 3 to 4 neutropenia and thrombocytopenia in the FDR gemcitabine arm, consistent with the earlier phase II trial. Of note, there was no survival advantage with the combination of gemcitabine and oxaliplatin. Based on these data, the fixed-dose rate of gemcitabine can be considered a reasonable alternative to the standard 30-minute gemcitabine infusion, albeit with greater toxicity.

A Decade of Failed Attempts to Move Beyond Gemcitabine Monotherapy

In addition to oxaliplatin, there have been numerous attempts over the past decade to augment the therapeutic benefit of gemcitabine in patients with advanced disease, using additional therapeutic agents in combination with gemcitabine (see Table 49.8). Conventional cytotoxic agents that have been tested include cisplatin, oxaliplatin, 5-FU, capecitabine, irinotecan, and exatecan. Despite promising phase II data, the aforementioned doublets all failed to show any benefit over gemcitabine monotherapy.^{174,220–228} In addition, novel targeted or biologic therapies have been tested in combination with gemcitabine, including marimastat (metalloproteinase inhibitor), tipifarnib (a farnesyltransferase inhibitor, targeting Kras signaling), cetuximab (epidermal growth factor receptor [EGFR] inhibitor), bevacizumab (angiogenesis inhibitor), and axitinib (multitarget tyrosine kinase inhibitor).^{229–233} In general, the addition of these agents to gemcitabine failed to markedly change OS.

A few of the biologic agents warrant special mention based on the promise of therapeutic efficacy in other cancer types or in early phase clinical trial data in the treatment of advanced PDA. EGFR is expressed in 60% of PDAs,¹⁶² and amplification or high polysomy at the EGFR locus is identified in half of the affected patients.²³⁴ Moreover, targeting EGFR is effective in certain nonpancreatic cancers (e.g., lung, colorectal, head and neck). Therefore, there is a strong therapeutic rationale for targeting EGFR in the treatment of PDA. Cetuximab is a monoclonal antibody with affinity for EGFR, which was tested in a small phase II study in patients with advanced pancreatic cancer as a combination therapy with gemcitabine.²³⁵ In the 41 patients with EGFR-positive tumors, the median OS was 7.1 months with a 1-year OS of 31.7%, suggesting a potential benefit when compared to historical controls.¹⁷¹ However, in the large and definitive phase III trial conducted by the Southwest Oncology Group (SWOG S0205),²³² this combination failed to improve the outcome of patients when compared

to gemcitabine alone. A total of 745 patients were accrued, with median survivals of 6.3 (combination) and 5.9 months, respectively ($p = 0.23$). Objective response rates and progression-free survival were also similar between the two groups.

Angiogenesis has proven to be a worthy target in the solid tumor arena, and prior successes served as the impetus for the Cancer and Leukemia Group B (CALGB 80303) double-blind, placebo-controlled randomized phase III trial comparing gemcitabine plus bevacizumab versus gemcitabine alone.²³¹ A total of 602 treatment-naïve patients with advanced pancreatic cancer were accrued. The median OS were 5.8 and 5.9 months, respectively ($p = 0.95$). Again, response rates and progression-free survival were similar. Axitinib is another antiangiogenic factor, and a potent inhibitor of vascular endothelial growth factor receptor (VEGFR)1, 2, and 3. A randomized phase II trial with 103 patients demonstrated a nonsignificant improvement in OS; this prompted a larger phase III trial comparing gemcitabine 1,000 mg/m² on days 1, 8, and 15 every 28 days plus axitinib 5 to 10 mg orally daily, or gemcitabine plus placebo.²³⁰ There were 632 patients in the trial, which closed at an interim analysis when the futility boundary was crossed. Median OS was 8.5 months in the gemcitabine/axitinib arm and 8.3 months in the gemcitabine/placebo arm.

Two recently published meta-analyses examined the numerous randomized controlled clinical trials of gemcitabine-based combination therapy in aggregate. These studies included more than 8,000 patients enrolled in over 25 trials.^{236,237} Despite the fact that virtually all of these studies were negative independently, both meta-analyses found a small survival benefit (OR >0.9 with $p < 0.05$) with combination therapy, although toxicity was higher. Although these findings do not justify routine use of the examined regimens, they suggest that a small subset of patients (~10% to 20%) do receive a benefit and affirm that further work to identify the best candidates for specific combination therapies is warranted.

Modest Breakthroughs in the Treatment of Advanced Pancreatic Cancer

Two additional treatments have been approved for the treatment of advanced PDA by the FDA: erlotinib and nab-paclitaxel. The former drug is an oral tyrosine kinase inhibitor of the EGFR that was approved in 2005 for use in combination with gemcitabine for locally advanced unresectable or metastatic pancreatic cancer.¹⁷⁵ The National Cancer Institute of Canada Clinical Trials Group (NCIC-CTG) conducted a large international phase III double-blind randomized trial of 569 patients with advanced or metastatic pancreatic adenocarcinoma, comparing gemcitabine intravenous (IV) 1,000 mg/m² weekly \times 7 weeks followed by 1 week of rest, then weekly \times 3 every 4 weeks plus erlotinib 100 mg or 150 mg per day orally versus gemcitabine plus placebo. Toxicities, including diarrhea and the typical acneiform rash associated with EGFR inhibitors, were slightly worse in the erlotinib arm. Nevertheless, these toxicities were mostly grade 1 to 2 and easily manageable. The gemcitabine/erlotinib arm experienced an improved median OS (6.24 months versus 5.91 month), with 1-year OS of 23% and 17%, respectively. Based on this study, combination gemcitabine and erlotinib became a standard of care in the first-line treatment of locally advanced or metastatic pancreatic cancer in patients with a reasonably good performance status at many centers. Enthusiasm for the combination has certainly been tempered by the fact that the survival benefit amounted to just 10 days with the combination therapy. Moreover, erlotinib adds roughly \$10,000 per month to the cost of treatment.²³⁸ With that said, gemcitabine/erlotinib is clearly a more effective treatment for a subgroup of 5% to 10% of patients than gemcitabine monotherapy, and identifying predictive markers to select these individuals would be a significant advance and a step towards personalized treatment for pancreatic cancer. Notably, individuals who experienced a skin rash had improved disease control ($p = 0.05$) and improved survival

(Cox regression HR = 0.37; p = 0.04). Kras mutation status was tested based on prior data that wild-type Kras in colorectal cancers is predictive of response to anti-EGFR therapy.²³⁹ Unfortunately, no such correlation was found, although the study was underpowered, in large part because nearly all PDAs harbor Kras mutations.²³⁴

Building on the modest success of the gemcitabine/erlotinib doublet, Van Cutsem et al.²⁴⁰ evaluated the same combination with or without bevacizumab in a randomized phase III study (published prior to the negative phase III gemcitabine/bevacizumab study).²⁴⁰ Six hundred and seven patients were randomized to receive gemcitabine 1,000 mg/m² per week × 7 weeks over 8 weeks and × 3 every 4 weeks for subsequent cycles plus erlotinib 100 mg per day and bevacizumab 5 mg/kg every 2 weeks, or gemcitabine/erlotinib plus placebo. The median OS were 7.1 months for the bevacizumab arm and 6.0 months for the control arm (p = 0.2). Of note, there was an improvement in progression-free survival with the experimental treatment (4.6 versus 3.6 months; p = 0.0002). Grade 3 through 5 adverse events were comparable. Although the primary end point of OS was not met, there was an apparent favorable trend across all end points, providing a modicum of optimism that the gateway towards improved outcomes was opening, if ever so slightly.

Nab-paclitaxel was approved by the FDA in September 2013 as a second agent indicated for combination therapy with

gemcitabine. Paclitaxel binds with high affinity to microtubules, thereby stabilizing tubule polymerization and inhibiting cell mitosis. Nab-paclitaxel is bound to albumin, resulting in improved pharmacokinetic efficiency and higher intratumoral drug levels, compared to the standard solvent-based paclitaxel formulation (standard paclitaxel pharmacokinetics is otherwise limited by the hydrophobic nature of the molecule).²⁴¹ The exact mechanism of improved nab-paclitaxel delivery is not completely understood, but evidence points to protein-protein interactions between albumin and receptors that mediate transport (e.g., gp60) or that enhance drug targeting in the stroma (secreted protein, acidic, cysteine-rich [SPARC]).²⁴² Interestingly, a recent study of drug pharmacokinetics in a genetically engineered SPARC-null mouse demonstrated that intratumoral nab-paclitaxel levels were not dependent on SPARC expression and that the drug does not target the stroma in this model.²⁴³

In an early phase I/II study, gemcitabine 1,000 mg/m² with nab-paclitaxel 125 mg/m² weekly × 3 every 28 days, resulted in tumor shrinkage in 48% of patients (substantially higher than the 5% rate previously seen with gemcitabine alone¹⁷¹) and a median OS of 12.2 months (more than twice the survival with gemcitabine).²⁴⁴ With these promising results, a large international phase III study was conducted, randomizing 861 patients with advanced PDA to receive either gemcitabine/nab-paclitaxel or gemcitabine alone.¹⁷⁸ The MPACT study met its primary end point (Fig. 49.8), with a

Overall survival

No. at risk

Progression-free survival, according to independent review

No. at risk

nab-Paclitaxel-Gemcitabine	431	281	122	62	24	8	4	2	0
Gemcitabine	430	209	51	23	10	6	4	0	0

B

Figure 49.8 Kaplan-Meier curves for survival and progression-free survival for nab-paclitaxel versus gemcitabine. CI, confidence interval. (From Von Hoff DD, Ervin T, Arena FP, et al. Increased survival in pancreatic cancer with nab-paclitaxel plus gemcitabine. *N Engl J Med* 2013;369:1691-1703.)

median OS of 8.5 months in the gemcitabine/nab-paclitaxel arm and 6.7 months in the gemcitabine group ($p < 0.001$). Progression-free survivals were 5.5 and 3.7 months, respectively ($p < 0.001$). The 1-year OS were 35% versus 22%, and the 2-year OS were 9% versus 4%, respectively. Patients receiving combination therapy had a higher response rate as well (23% versus 7%; $p < 0.001$). Grade 3 or higher toxicities that were more common in the nab-paclitaxel arm included neutropenia (38% versus 27%), fatigue (17% versus 7%), and neuropathy (17% versus 1%). Given the results of this trial, gemcitabine combined with nab-paclitaxel has eclipsed gemcitabine plus erlotinib as a standard of care in the first-line treatment of advanced, unresectable, or metastatic pancreatic adenocarcinoma. Importantly, the cost of adding nab-paclitaxel is not trivial (\$8,000 per month).

Although gemcitabine has served as the principal backbone for pancreatic cancer therapy in most clinical trials, including patients with advanced PDA, studies were also being conducted on a combination of other drugs with proven success in colorectal cancer, including FOLFIRINOX. In 2003, the results of a phase I study were reported, which included 34 evaluable patients in total, and 6 with advanced pancreatic cancer. Two of the patients with pancreatic cancer experienced an objective response, with one complete responder.²⁴⁵ These observations spawned a single-arm phase II trial in 47 chemotherapy-naïve patients with advanced pancreatic

cancer.²¹⁰ In the 46 evaluable patients, the overall response rate was 26%, with a 4% complete response rate. Median time to progression was 8.2 months and the median OS was 10 months. A randomized phase II trial was initiated, comparing the regimen to gemcitabine. Promising results in 88 patients were presented at the American Society of Clinical Oncology (ASCO) 2007 conference (response rate of 38.7% versus 11.7%), and the study continued on as the large, randomized phase III PRODIGE 4/ACCORD 11 study.²⁴⁶

The PRODIGE 4/ACCORD 11 study randomized 342 patients with a performance status of ECOG 0-1 to receive FOLFIRINOX (oxaliplatin 85 mg/m², irinotecan 180 mg/m², leucovorin 400 mg/m², and 5-FU 400 mg/m² IV bolus followed by 5-FU 2,400 mg/m² as a 46-hour continuous infusion every 2 weeks) versus gemcitabine 1,000 mg/m² weekly \times 7 weeks followed by 1 week of rest, then 3 times per weekly \times 3 every 4 weeks.¹⁷⁷ The primary end point was overall survival OS (Fig. 49.9). The FOLFIRINOX group had a median OS of 11.1 months compared to 6.8 months in the gemcitabine alone arm ($p < 0.001$). Median progression-free survivals were 6.4 months and 3.3 months ($p < 0.001$), respectively. Objective response rates were 31.6% versus 9.4% ($p < 0.001$), and disease control rates (response + disease stability) were 70.2% and 50.9%, respectively. The FOLFIRINOX regimen resulted in substantially more toxicity, including higher grade 3 and 4 neutropenia (45% versus 21%), febrile neutropenia (5.4%

A

B

Figure 49.9 Kaplan–Meier curves for survival and progression-free survival for FOLFIRINOX. (From Conroy T, Desseigne F, Ychou M, et al. FOLFIRINOX versus gemcitabine for metastatic pancreatic cancer. *N Engl J Med* 2011;364:1817–1825.)

versus 1.2%), thrombocytopenia (9.1% versus 3.6%), diarrhea (12.7% versus 1.8%), and sensory neuropathy (9% versus 0%). Despite these significant side effects, only 31% of patients in the FOLFIRINOX group had a definitive degradation in quality of life (QoL), as compared to 66% in the gemcitabine group. The time to definitive deterioration (based on the EORTC QoL questionnaire) was also significantly longer for the FOLFIRINOX group in the areas of global health status; physical, cognitive, and social functioning; and multiple symptom domains (e.g., fatigue and pain).²⁴⁷

Finally, a recently reported phase III trial in Japan compared gemcitabine alone (standard dosing) versus S-1 alone (80 to 120 mg per day for 28 days every 42 days) versus the combination of gemcitabine (1,000 mg/m² × 2 every 21 days) plus S-1 (60 to 100 mg per day for 14 days every 21 days). S-1 is an oral fluoropyrimidine derivative available in Japan with activity against PDA. A total of 832 patients with locally advanced or metastatic PDA were included in the analysis. OS were 8.8, 9.7, and 10.1 months ($p = 0.15$ for combination therapy compared to gemcitabine alone), respectively. Objective responses were higher with S-1 monotherapy (21%) and combination therapy (29%), than gemcitabine alone (13%). Gemcitabine was associated with more hematologic toxicities compared to S-1, whereas S-1 was associated with more diarrhea.²⁴⁸ Combination therapy was the most toxic regimen.

Taken together, these trials establish gemcitabine alone, S-1 (in Japan), gemcitabine plus nab-paclitaxel, gemcitabine plus erlotinib, and FOLFIRINOX as the current standard of care treatments for metastatic pancreatic cancer. The latter regimen is recommended for patients with excellent performance status (ECOG 0 or 1), whereas the other regimens are applicable for a broader patient population (ECOG 0–2).

Monitoring Treatment Response

In the current era, with multiple active drugs available to treat PDA, patients increasingly have second-line options after a first-line therapy fails. Therefore, it is important for oncologists to closely monitor patients for signs of progression. Patients typically have weekly laboratory testing, and are seen biweekly or monthly by medical oncologists who assess for signs of treatment toxicity. With regard to treatment response, patients undergo repeat imaging (CT scans or magnetic resonance imaging [MRI]) every 8 weeks and responses are assessed by Response Evaluation Criteria in Solid Tumors (RECIST) criteria. CA 19-9 levels are serially drawn every 8 weeks. A falling CA 19-9 level in response to treatment is associated with improved survival, with the greatest decreases being associated with the best outcomes.^{249–253} CEA and CA-125 are not FDA-approved biomarkers for PDA, and have far less accuracy than CA 19-9. Nevertheless, they may be helpful to monitor response to therapy, particularly in patients who do not express CA 19-9 due to Lewis antigen polymorphism variability. In the face of rising tumor markers and tumor progression, oncologists should pay close attention to performance status, because patients with an ECOG status of 2 or greater have an expected survival around 2 months and are not likely to benefit from additional chemotherapy.²³¹

Symptom Palliation

Although extending survival is a primary objective in patients with PDA, the palliation of symptoms is equally important. As with other aspects of care, palliative-focused therapy in the patient with PDA requires a multidisciplinary team approach. Treatment recommendations are often based on the etiology of the symptoms, which may be multifactorial. Contributing factors include the metabolic burden of the tumor, treatment toxicity, or mechanical obstruction from the tumor. Optimization of nutritional intake is paramount and could be exacerbated by cancer cachexia and pancreatic insufficiency. Aggressive pain management frequently

requires minimally invasive interventions such as celiac plexus neurolysis (endoscopic or percutaneous), in addition to systemic narcotics. Active surveillance and prompt treatment of thromboembolic events, biliary obstruction, and gastric outlet obstruction are critical. Psychosocial issues for the patient and family must be addressed. Often, the extent of symptoms and deterioration in performance status precludes additional antitumor-directed therapy. Even with expert care, there is a 1% to 4% mortality rate related to treatment.^{177,178} Therefore, oncologists need to have frank discussions with patients and family members about best supportive care (e.g., no chemotherapy or radiation) when appropriate.

FUTURE DIRECTIONS AND CHALLENGES

The timeline of pancreatic cancer therapy can be summarized as follows (Fig. 49.10): Through the 1970s, no effective therapies existed; between 1980 and 2000, surgical outcomes markedly improved, permitting safe treatment of early stage PDA at high volume centers; between 2000 and the present, modest improvements in chemotherapy and radiation have improved outcomes and the safety profile of these treatments. Over the same time span, there have been dramatic advances in the genetic and molecular understanding of pancreatic cancer development and survival, although this new knowledge has not yet translated into improved patient outcomes. It is becoming more apparent, however, that the field is on the cusp of substantial breakthroughs, similar to those experienced recently in many other cancer types (e.g., breast, colon, melanoma). The next decade will likely produce improved molecular diagnostics (markers for detection, prognosis, and treatment response), targeted therapies (personalized oncology), antistromal agents used in tandem with antineoplastic agents, and immunotherapies (e.g., vaccines and immune checkpoint inhibitors). There is a growing trend toward multi-institutional collaboration fostered by the National Cancer Institute (NCI), private foundations, and industry, as well as scheduled national meetings focused entirely on pancreatic cancer research. This surge in collaboration and communication between thought leaders, coupled with increased national attention (e.g., the Recalcitrant Cancer Research Act of 2012, which identified pancreatic cancer as a high priority), will undoubtedly jolt the field forward in the coming years.

In this closing section, we will broadly discuss some of the most encouraging areas of research, address some of the greatest challenges, and highlight areas that warrant investigative pursuit.

Biomarkers: Diagnostic, Prognostic, and Predictive

Biomarkers can be separated into three categories. *Diagnostic* biomarkers detect the presence of disease. They are relevant for *early detection*, as well as to measure disease burden in response to therapy. *Prognostic* markers gauge disease aggressiveness or tumor biology, and are used to forecast outcome or recurrence pattern. *Predictive* markers predict treatment response, and are the key ingredient to a personalized therapeutic approach.

Figure 49.10 Timeline of advances in PDA-related therapy and science.

Effective early detection of PDA could have the greatest impact on PDA-specific outcomes, but may also be the least likely to come to fruition. Such a test would need to identify premalignant lesions that are at very high risk of developing into an invasive lesion (PanIN-3). Genetically engineered mouse data suggest that tumor dissemination can still occur even at the premalignant stage²⁵⁴; nevertheless, it is still believed (albeit unproven) that treatment of PanIN-3 lesions would be curative for most patients. Moreover, PanIN-3 (i.e., carcinoma in situ) lesions are likely far enough along in the tumor progression sequence that the risk of overtreatment would not outweigh the potential benefit of treatment (including surgical intervention).^{33,255}

There are several challenges associated with early detection research. First, most diagnostic biomarker research to date merely distinguishes invasive PDA (in resected patients) from normal controls. This research largely misses the point, because the index lesions are not *curable* precursor lesions. Most individuals with *localized* invasive cancer already harbor occult metastases. Presently, only 6% of resected PDAs (and <1% of all PDAs) are diagnosed at stage I, and the resection of PanIN-3 disease in the absence of invasive carcinoma is exceedingly rare.^{27,256} Second, current CT scanning technology fails to reliably detect PDAs below 2 cm, because PDAs are poorly demarcated and are hypodense compared to normal pancreata.⁵⁰ Curable lesions (i.e., PanIN-3 lesions) are likely one-quarter the size of this lower limit.²²⁴ Third, the sensitivity required for effective screening tests is much higher than commonly appreciated. Pannala et al.⁷⁹ calculated that an early detection biomarker with 99% sensitivity and specificity would detect all PDAs in the general population, but would also result in a 1% false positive rate due to the relatively low prevalence of PDA (false positives outnumbering true positives by an astounding 25:1). Restricting early detection tests to *high-risk* individuals would improve the positive predictive value, but of course end up missing sporadic PDAs, which comprise the large majority of cases. Finally, serum based tests have a low pretest probability of detecting molecular analytes derived from *non-invasive* lesions that do not have access to the circulatory system. As an illustration of this point, we recently prepared plasma from fresh phlebotomy draws in patients with PDA, and performed a Kras mutation screen using a high-sensitivity commercial mutation detection assay (BEAMing, which detects mutant genes in a background of wild-type DNA at ratios >1:10,000).²⁵⁷ Mutations were detected at low rates even in patients with high invasive disease burden: two out of nine patients with metastatic disease and zero out of three with localized disease (Jordan M. Winter, unpublished observation). With improved high-throughput instrumentation and bioinformatics strategies available, researchers are now better equipped to interrogate analytes beyond DNA (e.g., metabolome, transcriptome, proteome) in search of a molecular beacon of early PDA. National tissue banking programs, such as the NCI-sponsored Early Detection Research Network, are critical to this pursuit.

There are currently no effective prognostic panels for PDA, akin to the validated Oncotype Dx panels for breast, colon, and prostate cancers. Limitations are primarily due to relatively low tissue availability and to a tighter survival distribution necessitating even higher sample numbers for analyses. Nevertheless, the technology currently exists (e.g., gene expression arrays or Nanostring multiplex gene expression analyses [Seattle, WA]) to develop prognostic panels for PDA. Improved prognostics could identify patients who harbor particularly aggressive tumors that may appear resectable by imaging, yet are best managed with neoadjuvant chemotherapy to treat occult metastases and perhaps avoid ineffective surgery.

There has been some intriguing work in this area. Stratford et al.²⁵⁸ used fresh frozen tumors from 15 resected PDAs and 15 metastatic PDAs (from autopsies) to identify a gene expression signature using cDNA microarrays associated with metastatic disease. The researchers then tested the derived signature in two sepa-

rate cohorts of patients with resected disease and found that the panel predicted poor survival. The gene signature has not yet been validated by a separate group.²⁵⁸ In a separate study, protein expression patterns of 13 putative PDA biomarkers were examined in a large cohort of short- and long-term survivors after resection. The investigators found that MUC1 and mesothelin (MSLN) expression were far more predictive of early cancer-specific death than conventional pathologic features. Again, these findings require validation.¹⁶²

There are no proven predictive markers for standard pancreatic cancer therapies. Data from the phase II gemcitabine/nab-paclitaxel study suggested that stromal SPARC expression is associated with improved outcome.²⁴⁴ Data from the more recent phase III study are forthcoming. No predictive markers of gemcitabine have been consistently validated in samples from randomized trials. Human equilibrative nucleoside transporter 1 (hENT1) is a nucleoside transporter involved in gemcitabine uptake. Increased expression was associated with improved survival in patients receiving gemcitabine in the RTOG 9704 study,²⁵⁹ but no association was observed in a randomized study comparing gemcitabine and an hENT1-independent gemcitabine derivative.²⁶⁰ Brody et al. have identified the RNA binding protein, HuR, as a candidate predictive marker of gemcitabine efficacy in two retrospective institutional cohorts.^{261,262} HuR regulates and stabilizes DCK, which phosphorylates and activates gemcitabine. Investigators are currently evaluating samples from the adjuvant ESPAC3 trial (gemcitabine versus 5-FU) to validate this finding. Finally, our group at Thomas Jefferson recently observed that DCK expression was associated with improved survival in patients receiving 5-FU chemotherapy in the RTOG 9704 trial. This finding was recapitulated in cell lines (unpublished).

Targeted Therapy

As a result of whole-exome sequencing, the vast majority of genes mutated in PDA with high frequency are now known. Unfortunately, no novel high frequency *druggable* targets were identified. Many mutated genes can be categorized within core signaling pathway (12 were initially described),³⁵ and there have growing efforts to try to develop therapies targeting these pathways (as opposed to a specific genetically altered gene). In addition, there has been a redoubling of efforts to target Kras, as a result of the empty genetic search for promising new targets. As stated, Kras is mutated in virtually every PDA, as well as most cells within each PDA. Although attempts to inhibit Kras have eluded researchers thus far, numerous innovative approaches are currently under investigation. These include developing novel compounds to directly bind and inhibit RAS through rational drug design; developing drugs that restore GTP hydrolytic function in mutant RAS; interference with RAS posttranslational modification (e.g., prenylation, proteolytic processing, carboxyl methylation); inhibition of RAS expression (e.g., RNA interference); inhibition of downstream RAS signaling (e.g., Raf-MEK-ERK and PI3K pathways); and identifying pathways that are required for survival in Kras mutant cells (synthetic lethal approach). As evidence of the importance that the NCI has placed on this research, the NCI recently announced an initiative focused on targeting Kras, and plans to divert \$10 million annually to support the program (<http://frederick.cancer.gov/News/RASCancerGeneticsInitiative.aspx>).

Heterogeneity as an Obstacle to Targeted Therapy

PDAs exhibit tremendous molecular heterogeneity, both between and within tumors. The genetic fingerprint of each tumor is unique: each with a different set of mutated genes and chromosome copy number changes.^{35,41} Yachida et al.²⁵⁵ revealed that

Figure 49.11 MUC1 expression in a pancreatic cancer. A focus of invasive cancer reveals areas of positive (+) and negative (–) MUC1 expression (arrows).

genetic abnormalities differ across a given pancreatic tumor, with genetically distinct foci in the primary, that give rise to clonal populations in metastatic deposits. An immunohistochemical survey of pancreatic cancer biomarkers illustrates the diversity in protein expression.¹⁶² For instance, MUC1 is absent in 15% of PDAs, but is diffusely expressed (>75% of neoplastic cells) in 30%. Even a single focus of PDA containing both MUC1-positive and MUC1-negative cells illustrates biologic variation within a given tumor (Fig. 49.11). Keeping with this pattern, metabolic gradients exist in tumors due to the proximity of neoplastic cells to patent blood vessels as well as due to the dynamic nature of the tumor microenvironment. Microecologic niches result,²⁶³ which are reflected in the varied expression patterns of metabolic enzymes across tumor sites (e.g., primary and metastases) in patients with PDA.²⁶⁴ Basic cell cycle dynamics drive proteomic changes in a single cell over time, even in the most stable circumstances. PDA heterogeneity is, therefore, a certainty, yet has emerged as the unaddressed truth, as the cancer field pursues a *personalized* approach to cancer therapy. Single molecule targeting is likely to fail because of PDA heterogeneity. An example from another cancer type is illustrative. Extreme heterogeneity, based on the expression pattern of the estrogen receptor, was observed in a human ovarian cancer prior to treatment. After treatment, the expression pattern was dramatically altered in the same tumor sample, when only chemoresistant clones survived.²⁶⁵ A multitargeted approach may be necessary, similar to the standard treatment strategy against HIV. Therapeutic strategies that are significantly more *tunable* than conventional medicinal pharmacology may also be useful, such as nanoparticle-delivered gene therapy.²⁶⁶

Targeting the Stroma

Over 70% of a PDA is comprised of stroma, and a worse outcome was observed in patients with tumors exhibiting a higher stromal content.²⁶⁷ The hypovascular stroma is viewed as an obstacle to drug delivery, and explains why gemcitabine is potent against

xenografts (with low stromal content), but ineffective in autochthonous genetically engineered mouse models of PDA.²⁶⁸ Stromal depletion in KPC mice (mice with conditional and pancreatic-specific expression of mutant Kras and TP53) with a Hedgehog pathway inhibitor improved gemcitabine delivery to tumors and decreased tumor burden. The same effects were observed in a separate study that used a drug targeting the extracellular matrix protein, hyaluronic acid.²⁶⁹ Thus, targeting the tumor stroma is a promising strategy to improve the efficacy of conventional pancreatic cancer treatments and is a high research priority.

Metabolism

There is a growing appreciation and understanding of the malignant metabolic phenotype, although Otto Warburg first observed fundamental metabolic differences between cancer and normal cells nearly 100 years ago. The proliferative demands of pancreatic cancer cells, along with the adaptive requirements for survival in an austere tumor microenvironment (characterized by an abundant, yet nutrient-deprived stroma), require complex mechanisms to reprogram metabolic pathways.²⁷⁰ In fact, PDA cells are particularly tolerant to nutrient deprivation compared to other cancers.³¹ Recently, mutant Kras was found to alter metabolic pathways, leading to increased glycolysis,²⁷¹ altered amino acid metabolism through noncanonical enzyme pathways,²⁷² and macropinocytosis of protein as an additional fuel source.²⁷³ Metabolic reprogramming through posttranscriptional regulation of metabolic enzymes by a stress response RNA-binding protein was found to be an independent survival mechanism of PDA cells under nutrient deprivation.²⁷⁴ A better understanding of PDA metabolism will likely expose metabolic dependencies as important therapeutic targets.

Immunotherapy

Immunotherapy was the 2013 Science Breakthrough of the Year,²⁷⁵ as a result of multiple new therapies for nonpancreatic malignancies (especially melanoma). Many of the treatments work by targeting immunologic checkpoints (i.e., immunosuppressive pathways induced by cancer cells). Inhibition of these molecules with antibodies unleashes the body's immune system against the tumor in some patients.^{276,277} T-cell adoptive therapy is another emerging immunotherapy with successes in nonpancreatic cancers, where T cells from patients are genetically engineered *ex vivo* to target the patient's own tumor.²⁷⁸ Thus, there is an urgent need to understand how these strategies can be used or modified to treat pancreatic cancer.

There are immunotherapies that have had some preclinical and early clinical trial success against pancreatic cancer. CD40 is a molecule on the surface of tumor-associated macrophages that stimulates T-cell-dependent antitumor immunity. In a recent phase I study, patients with treatment-naïve advanced PDA were treated with gemcitabine and a monoclonal antibody that binds and stimulates CD40. There was a 19% response rate and biologic indicators of a strong immune response (e.g., increased cytokine levels).²⁷⁹ A pancreatic cancer vaccine (algenpantucel-L, New-Link Genetics Corporation, Ames, IA) has also been developed in which pancreatic cancer cell lines are genetically engineered to express an immunogenic nonhuman epitope. The vaccine is delivered intradermally, and was given to 70 patients as part of a phase II study, along with gemcitabine and chemoradiation (similar to the RTOG 9704 regimen). The 12-month OS of patients who received the vaccine and conventional adjuvant treatment was 86%, which compared favorably with historical controls.²⁸⁰ Vaccine-related toxicity was minimal. A phase III adjuvant trial was recently completed in North America, and the results are pending.

CONCLUSION

Improvements in pancreatic cancer treatment over the past 2 decades include safer surgical management, safer radiation treatment, and modest but notable improvements in systemic treatments. With modern chemotherapy, roughly half of patients experience temporary disease control. Nevertheless, the disease

is still lethal in most patients and survival beyond 2 years is a rare event. For those of us who routinely treat this disease, progress cannot come soon enough. However, advances are imminent, and there is reason for optimism. The Pancreatic Cancer Action Network has publicized its desire to dramatically improve patient outcomes by the year 2020, and the scientific community is rallying to the charge.

50 Genetic Testing in Pancreatic Cancer

Jennifer E. Axilbund and Elizabeth L. Wiley

INTRODUCTION

It is estimated that 5% to 10% of pancreatic cancer (adenocarcinoma) is familial,^{1,2} and individuals with a family history of pancreatic cancer are at a greater risk of developing pancreatic cancer themselves.³ Although there is evidence of a major pancreatic cancer susceptibility gene,⁴ it remains elusive. Therefore, the majority of families with multiple cases of pancreatic cancer do not have an identifiable causative gene or syndrome, making risk assessment and counseling challenging. However, a subset of pancreatic cancer is attributable to known inherited cancer predisposition syndromes (Table 50.1).

SELECTED GENES THAT MAY CAUSE PANCREATIC CANCER

BRCA2

The *BRCA2* gene is associated with hereditary breast and ovarian cancer syndrome, and often presents as premenopausal breast cancer, ovarian cancer, and/or male breast cancer. The Breast Cancer Linkage Consortium⁵ reported a 3.5-fold (95% confidence interval [CI], 1.9 to 6.6) increased risk of pancreatic cancer in *BRCA2* gene mutation carriers. Subsequent studies in the United Kingdom and the Netherlands showed a relative risk of 4.1 and 5.9, respectively.^{6,7} In a United States–based study, 10.9% (17 out of 156) of families with a *BRCA2* mutation reported a family history of pancreatic cancer. The median ages at diagnosis for males and females were 67 and 59 years, respectively, which differed statistically from the Surveillance, Epidemiology and End Results (SEER) database (70 years old for males and 74 years old for females; $p = 0.011$).⁸ Although genotype–phenotype data remain sparse, the *BRCA2* K3326X variant was found in 5.6% (8 out of 144) of familial pancreatic cancer patients compared with 1.2% (3 out of 250) of those with sporadic pancreatic cancer (odds ratio [OR], 4.84; 95% CI, 1.27 to 18.55; $p < 0.01$).⁹

Approximately 17% of pancreatic cancer patients who have at least two additional relatives with pancreatic cancer carry deleterious mutations in the *BRCA2* gene.¹⁰ Estimates for the prevalence of *BRCA2* mutations with two first-degree relatives with pancreatic cancer are 6% to 12%,^{11,12} and *BRCA2* mutations also explain a portion of apparently sporadic pancreatic cancers.¹³ However, prevalence varies between populations. Out of 145 Ashkenazi Jews with pancreatic cancer, 6 (4.1%) were found to have a deleterious *BRCA2* mutation when compared with cancer-free controls (OR, 3.85; 95% CI, 2.1 to 10.8; $p = 0.007$), although no differences were noted in age at diagnosis or clinical pathologic features.¹⁴ An earlier, smaller study found a deleterious *BRCA2* mutation in 3 (13%) of 23 Ashkenazi Jews with pancreatic cancer, unselected for family history.¹⁵ Among Ashkenazi Jewish probands with breast cancer who reported a family history of pancreatic cancer, 7.6% (16 out of 211) had a *BRCA2* mutation.¹⁶ By comparison, no *BRCA2* mutations were found in studies of pancreatic cancer in Korea or Italy.^{17,18}

BRCA1

Similar to *BRCA2*, mutations in *BRCA1* are associated with a markedly increased risk for premenopausal breast cancer and ovarian cancer. The Breast Cancer Linkage Consortium reported a 2.26-fold (95% CI, 1.26 to 4.06) increased risk of pancreatic cancer in families with a *BRCA1* mutation,¹⁹ and Brose et al.²⁰ estimated a threefold higher lifetime risk. However, more recently, in the United Kingdom, Moran et al.⁹ found no elevation in pancreatic cancer risk in 268 families with a known *BRCA1* mutation. A United States–based study reported that 11% (24 out of 219) of their families with a *BRCA1* mutation had at least one individual with pancreatic cancer, with median ages at diagnosis of 59 years for males and 68 years for females. Again, this was significantly younger than reported in the SEER database ($p = 0.0014$).⁸ Al-Sukhni et al.²¹ molecularly evaluated pancreatic tumors from seven known *BRCA1* mutation carriers and found a loss of heterozygosity of *BRCA1* in five (71%), with confirmed loss of the wild-type allele in three of the five compared with only one (11%) of nine sporadic controls. This suggests that *BRCA1* germ-line mutations do, in fact, predispose some individuals to pancreatic cancers.

Familial breast cancer registries in the United States and Israel have evaluated the mutation status of families that reported pancreatic cancer in addition to breast cancer and ovarian cancer. In the US study of 19 families with breast, ovarian, and pancreatic cancer, 15 carried a deleterious mutation in *BRCA1* and 4 in *BRCA2*,²² whereas the Israeli study reported an equal number of *BRCA1* and *BRCA2* families.²³

Another study, specifically of Ashkenazi Jewish families, reported a *BRCA1* mutation in 7% of probands with breast cancer who also had a family history of pancreatic cancer,¹⁶ which was, again, equal to the prevalence of *BRCA2* mutations. Thus, within the Ashkenazi Jewish population, *BRCA1* and *BRCA2* mutations may contribute more equally to risk in families with both breast and pancreatic cancer. However, these studies all examined cohorts of families selected because of clustering of breast and/or ovarian cancer with pancreatic cancer. When families were selected on the basis of familial pancreatic cancer alone, *BRCA1* mutations were less prevalent. None of the sixty-six families with three or more cases of pancreatic cancer had a deleterious *BRCA1* mutation, including those who also reported a family history of breast and/or ovarian cancer.²⁴ An evaluation of Ashkenazi Jewish patients ascertained on the basis of pancreatic cancer alone showed a 1.3% (2 out of 145) prevalence of *BRCA1* mutations.¹⁴ Therefore, *BRCA1* may explain a small subset of families showing a clustering of pancreatic cancer with breast and/or ovarian cancer, but is unlikely to explain most families with site-specific pancreatic cancer.

PALB2

PALB2 (partner and localizer of *BRCA2*) was recognized as the *FANCN* gene in 2007, and biallelic mutation carriers develop

TABLE 50.1

Inherited Cancer Predisposition Syndromes that Increase the Risk for Pancreatic Cancer

Syndrome	Gene(s)	Risk of Pancreatic Cancer	Predominant Features
Hereditary breast and ovarian cancer	<i>BRCA1</i>	RR, 2.26–3	Malignancies: Breast (particularly premenopausal), ovary, male breast, prostate
	<i>BRCA2</i>	RR, 3.5–5.9	Malignancies: Breast (particularly premenopausal), ovary, male breast, prostate, melanoma (cutaneous and ocular)
Familial atypical multiple mole and melanoma	<i>CDKN2A</i>	RR, 7.4–47.8	Malignancies: Melanoma (often multiple and early onset) Other: Dysplastic nevi
Hereditary pancreatitis	<i>PRSS1</i>	SIR, 57	Other: Chronic pancreatitis
Hereditary nonpolyposis colorectal cancer (Lynch syndrome)	<i>MLH1</i> <i>MSH2</i> <i>MSH6</i> <i>PMS2</i> <i>EPCAM</i>	SIR, 0–8.6	Malignancies: Colorectum, endometrium, ovary, stomach, small bowel, urinary tract (ureter, renal pelvis), biliary, brain (glioblastoma), skin (sebaceous)
PJS	<i>STK11</i>	SIR, 132	Malignancies: Colorectum, small bowel, stomach, breast, gynecologic Other: Melanin pigmentation (mucocutaneous), small-bowel intussusception

SIR, standardized incidence ratio.

Fanconi anemia.^{25,26} Monoallelic mutation carriers were shown to be at an increased risk for breast cancer (relative risk [RR], 2.3; 95% CI, 1.4 to 3.9).²⁷ The prevalence of *PALB2* mutations among familial breast cancer cases is low across ethnicities; *PALB2* mutations are relatively nonexistent in breast cancers in the Irish and Icelandic populations and are found in approximately 1% of Italians, African Americans, Chinese, and Spanish breast cancer families, and in 2% of young South African breast cancer patients.^{28–35} An analysis of 1,144 US familial breast cancer cases found a *PALB2* mutation in 3.4% (33 out of 972) of non-Ashkenazi Jews and none (0 out of 172) of Ashkenazi Jews. The estimated risk for breast cancer was 2.3-fold by the age of 55 years (95% CI, 1.5 to 4.2) and 3.4-fold by the age of 85 years (95% CI, 2.4 to 5.9). There was also a fourfold risk for male breast cancer ($p = 0.0003$) and a sixfold risk for pancreatic cancer ($p = 0.002$).³⁶ Among French Canadian women with bilateral breast cancer, a *PALB2* mutation was found in 0.9% (5 out of 559) compared with none of the 565 women with unilateral breast cancer ($p = 0.04$), and first-degree relatives of *PALB2* mutation carriers had a 5.3-fold risk for breast cancer (95% CI, 1.8 to 13.2).³⁷

PALB2 founder mutations have been identified in several populations, including the c.2323C>T (Q775X) mutation in French Canadians.³⁸ Another example is the Finnish founder mutation c.1592delT. This mutation was found in 2.7% (3 out of 113) of familial breast and/or breast/ovarian cancer families compared with 0.2% (6 out of 2,501) of controls (OR, 11.3; 95% CI, 1.8 to 57.8; $p = 0.005$).³⁹ One percent (18 out of 1,918) of breast cancer cases unselected for family history also had this founder mutation. The hazard ratio for breast cancer was estimated at 6.1 (95% CI, 2.2 to 17.2; $p = 0.01$), with a penetrance of 40% by the age of 70 years.⁴⁰

PALB2 has not been shown to be a significant contributor to familial clustering of other cancers, including melanoma, ovarian cancer, and prostate cancer,^{41–43} but has been identified in familial pancreatic cancer kindreds. Specifically, Jones et al.⁴⁴ identified a *PALB2* mutation in a familial pancreatic

cancer proband, and subsequently found *PALB2* mutations in 3 out of 96 additional families, suggesting that 3% to 4% of familial pancreatic cancer may be attributed to this gene. Other populations have found lower mutation frequencies, ranging from absent in the Dutch (0 out of 31) to 3.7% (3 out of 81) in Germans.^{45,46} When ascertained on the basis of co-occurrence of breast and pancreatic cancer in the same individual or family, prevalence varied, again, from absent in the Dutch (0 out of 45) and United States–based studies (0 out of 77) to 4.8% (3 out of 62) in Italians.^{42,47,48}

CDKN2A

The p16 transcript of the *CDKN2A* gene is an important cell cycle regulator. Germ-line mutations in the *CDKN2A* gene predispose individuals to multiple early-onset melanomas. Somatic *CDKN2A* mutations are also frequently identified in pancreatic adenocarcinomas and precursor lesions, indicating a role for this gene in pancreatic cancer development and progression.^{49–51}

The risk of pancreatic cancer with *CDKN2A* mutations varies based on genotype. In a study of 22 families with the Dutch founder mutation, p16-Leiden, which is a 19–base-pair deletion in exon 2, the relative risk of pancreatic cancer was 47.8 (95% CI, 28.4 to 74.7).⁵² The age-related risks have been shown to be less than 1%, 4%, 5%, 12%, and 17% by ages 40, 50, 60, 70, and 75 years, respectively.⁵³ Regarding other mutations, the Genes, Environment and Melanoma Study assessed relative risks for nonmelanoma cancers in 429 first-degree relatives of 65 melanoma patients with a *CDKN2A* mutation. Five pancreatic cancers were reported compared with 41 pancreatic cancers among 23,452 first-degree relatives of 3,537 noncarriers, for a relative risk of 7.4 (95% CI, 2.3 to 18.7; $p = 0.002$).⁵⁴ A United States–based study estimated penetrance to be 58% by the age of 80 years (95% CI, 8% to 86%) and noted a hazard ratio of 25.8 ($p = 2.1 \times 10^{13}$) in those who ever smoked cigarettes.⁵⁵

Mutation prevalence in pancreatic cancer families varies by population. In an Italian study, 5.7% of 225 consecutive patients with pancreatic cancer had an identified *CDKN2A* mutation.⁵⁶ The predominant mutations were the E27X and G101W founder mutations, although others were also represented. Of 16 patients classified as having familial pancreatic cancer, 5 (31%) carried *CDKN2A* mutations, leading the authors to conclude that this gene may account for a sizeable subset of Italian familial pancreatic families. By comparison, no *CDKN2A* mutations were found in 51 Polish pancreatic cancer patients diagnosed at younger than 50 years.⁵⁷ Similarly, an analysis of 94 German pancreatic cancer patients who had at least one other first-degree relative with pancreatic cancer revealed no *CDKN2A* mutations.⁵⁸ However, two of five families with at least one pancreatic cancer and at least one melanoma had an identified mutation.⁵⁹ Similarly, a Canadian study found a *CDKN2A* mutation in 2 of 14 families with both pancreatic cancer and melanoma.⁶⁰ Finally, a United States–based study found 9 *CDKN2A* mutations in an unselected series of 1,537 pancreatic cancer cases (0.6%). The prevalence increased to 3.3% and 5.3% for those who reported a first-degree relative with pancreatic cancer or melanoma, respectively.⁵⁵ Thus, in the majority of populations, the co-occurrence of melanoma appears to be a significant indicator of an underlying *CDKN2A* mutation.

SELECTED SYNDROMES THAT INCREASE THE RISK OF PANCREATIC CANCER

Hereditary Nonpolyposis Colorectal Cancer

Hereditary nonpolyposis colorectal cancer (HNPCC), also referred to as Lynch syndrome, is the most common form of hereditary colon cancer, and it accounts for 2% to 5% of colorectal cancers. In addition to a high lifetime risk for colorectal cancer, affected individuals are at an increased risk for multiple other cancers. HNPCC results from mutations in mismatch repair (MMR) genes, and colon cancers that arise in Lynch syndrome typically demonstrate microsatellite instability (MSI). Four percent of all pancreatic adenocarcinomas demonstrate MSI.⁶¹ Yamamoto et al.⁶² assessed tumor characteristics in three *MLH1* mutation carriers with both colon and pancreatic cancer, and found that both tumor types had similar properties, including high MSI, loss of *MLH1* protein expression, wild-type *KRAS* and *p53*, and poor differentiation. These findings support an inherited basis for the development of both types of cancer.⁶²

Pancreatic cancer has been described in HNPCC kindreds as early as 1985, although data regarding the risk of pancreatic cancer in HNPCC have varied.^{63–68} Barrow et al.⁶⁴ studied 121 families with known MMR mutations; 2 of 282 extracolonic cancers were pancreatic, leading to a 0.4% cumulative lifetime risk for pancreatic cancer (95% CI, 0% to 0.8%). By comparison, Geary et al.⁶⁵ studied 130 families with MMR mutations and found 22 cases of pancreatic cancer, half of which were in confirmed or obligate carriers. Pancreatic cancer in these families was seven times more common than expected, and the familial relative risk was 3.8 ($p = 0.02$). In addition, these tumors were 15 times more common in individuals younger than 60 years, suggesting an earlier average age at diagnosis as compared with the general population.⁶⁵ Another United States–based study of HNPCC families found the lifetime risk for pancreatic cancer to be 1.31% by the age of 50 years (95% CI, 0.31% to 2.32%) and 3.68% by the age of 70 years (95% CI, 1.45% to 5.88%). These risks are higher than those from the SEER data of 0.04% and 0.52% at ages 50 and 70 years, respectively.⁶⁶

Regarding the prevalence of HNPCC in pancreatic cancer, Gargiulo et al.⁶⁹ assessed 135 pancreatic cancer patients. Nineteen of these patients had a family history that was suggestive of HNPCC, and of the 11 patients whose DNA was available for

analysis, only one deleterious MMR mutation was found. Thus, MMR mutations presumably account for only a small proportion of pancreatic cancer patients.

Hereditary Pancreatitis

Hereditary pancreatitis (HP) is a rare form of chronic pancreatitis. Several genes have been linked to chronic pancreatitis, including *SPINK1*, *CTFR*, and *CTRC*, but the *PRSS1* gene on chromosome 7q35 accounts for the majority of hereditary cases. *PRSS1* mutations are inherited in an autosomal-dominant fashion and have an 80% penetrance for pancreatitis. Affected individuals begin experiencing symptoms of pancreatic pain and acute pancreatitis early in life. Several studies have shown an increase in pancreatic cancer risk associated with HP, and cumulative lifetime risk estimates range from 18.8% to 53.5%.^{70–72} Lowenfels et al.⁷¹ observed an increased risk associated with paternal inheritance. Tobacco use in patients with HP has been shown to increase the risk for pancreatic cancer twofold (95% CI, 0.7 to 6.1), pancreatic and HP patients who smoke developed cancer 20 years earlier than did their non-smoking counterparts.⁷³

Peutz–Jeghers Syndrome

Peutz–Jeghers syndrome (PJS) is an autosomal-dominant condition characterized by mucocutaneous pigmentation and hamartomatous polyps of the gastrointestinal tract. PJS is caused by mutations on the *STK11* (*LKB1*) gene. The lifetime risk to develop any cancer has been estimated to be as high as 93%,⁷⁴ with no sex difference in cancer risk noted.^{74,75} Risk for pancreatic cancer in PJS is estimated to be 8% to 36% by the age of 70 years.^{74–76} Grützmann et al.⁷⁷ analyzed 39 individuals with familial pancreatic cancer, and none were found to carry mutations in *STK11*. In 2011, Schneider et al.⁵⁸ confirmed these findings in their study of 94 familial pancreatic cancer kindreds. Therefore, although *STK11* mutations confer a high lifetime risk for pancreatic cancer in individuals with PJS, germ-line *STK11* mutations are not thought to account for hereditary pancreatic cancer.

EMPIRIC RISK COUNSELING AND MANAGEMENT

Having a first-degree relative with apparently sporadic pancreatic cancer has a moderate effect on risk (OR, 1.76; 95% CI, 1.19 to 2.61).⁷⁸ In familial pancreatic cancer kindreds (defined as a family with a pair of affected first-degree relatives), the risk of pancreatic cancer increases with the number of affected first-degree relatives (Table 50.2).³ These findings suggest that high-penetrance genes may be causing the clustering of pancreatic cancer in families with two or three pancreatic cancer cases. Thus, individuals with multiple affected first-degree relatives are at an appreciably increased risk for pancreatic cancer and may be candidates for increased surveillance.

TABLE 50.2

Risk of Pancreatic Cancer in Familial Pancreatic Cancer Kindreds Based on Number of Affected First-Degree Relatives

Number of Affected FDRs	SIR (95% CI)
1	4.5 (0.54–16.3)
2	6.4 (1.8–16.4)
3	32 (10.4–74.7)

FDR, first-degree relatives; SIR, standardized incidence ratio.

Ideally, high-risk patients would be able to undergo noninvasive, inexpensive pancreatic cancer screening; however, to date, a highly sensitive and specific method for pancreas surveillance has not been recognized. Screening of high-risk patients with endoscopic ultrasound, magnetic resonance imaging, and/or magnetic resonance cholangiopancreatogram has been shown to be effective at identifying early neoplasms, both benign and

malignant.⁷⁹⁻⁸² However, it is unknown if these methods actually prevent pancreatic cancer or improve overall survival by detecting presymptomatic disease. In addition, there is great interest in developing a biomarker for premalignant or early-stage disease, although none, including CA19-9, have been proven effective.⁸³ Thus, whenever possible, it is recommended that high-risk patients undergo pancreatic screening through a research study.

51 Molecular Biology of Liver Cancer

Jens U. Marquardt and Snorri S. Thorgeirsson

INTRODUCTION

Hepatocellular carcinoma (HCC) is the fifth most common cancer in men and the seventh most common cancer in women worldwide, accounting for at least 600,000 deaths annually.¹ Although rates in traditionally high-incidence regions such as southeast Asia and sub-Saharan Africa has stabilized and slowly declined due to generalized vaccination programs, the incidence and mortality rates of HCC have doubled in the United States and Europe in the past 4 decades and are predicted to continue rising.² Several confounding factors (e.g., immigration from high-incidence countries) contribute to these high numbers in the western world, and HCC is currently among the fastest growing causes of cancer related deaths in the United States. Small HCCs can be cured by resection and/or liver transplantation. However, at the time of diagnosis, less than 20% of patients are eligible for these treatment options.³ These observations make it clear that liver cancer is a major health problem in the United States and Europe and highlight the critical need for both improved understanding and treatment options of this deadly disease.

The major etiologic agents responsible for chronic liver disease, cirrhosis, and ultimately, HCC are known and well characterized (e.g., hepatitis B virus [HBV], hepatitis C virus [HCV], ethanol abuse). Other etiologic factors include nonalcoholic fatty liver disease (NAFLD) and other metabolic disorders that have become particularly relevant in Western countries due to a sharp increase in prevalence and a high number of HCCs without underlying cirrhosis.⁴

Over the last decades, molecular mechanisms of liver diseases that are associated with increased risk of HCC as well as several cellular alterations that precede HCC have been identified.^{5,6} Research into the molecular pathogenesis of HCC is currently focused on the interrelationship of abnormal genomics, epigenomics, proteomics, and downstream alterations in molecular signaling pathways. The primary goal of this research is to integrate the new data with clinicopathologic features of HCC in order to uncover new diagnostic tools, improve treatment options, and implement effective prevention strategies.⁷

The recent introduction of next-generation whole genomic technologies permits simultaneously detection of the expression of tens of thousands of genes in small samples from normal and diseased tissues.⁸ High-throughput microarray-based technologies and the recent advent of next-generation whole genome DNA sequencing offer a unique opportunity to define the descriptive characteristics (i.e., phenotype) of a biologic system in terms of the genomic readout (e.g., gene expression, coding mutations, insertions and deletions in DNA, splicing variants, copy number variations, chromosomal translocations). Integrated analyses and the interpretation of biologic systems has caused a paradigm shift in biologic research, from the classic reductionism to systems biology.⁹ Fundamental to the systems approach is the hypothesis that disease processes are driven by aberrant regulatory networks of genes and proteins that differ from the normal counterparts. The application of multiparametric measurements promises to transform current

approaches of diagnosis and therapy, providing the foundation for predictive and preventive personalized medicine.¹⁰

In this chapter we discuss both the molecular hallmarks of hepatocarcinogenesis in the context of next-generation high-throughput genomic technologies, and the implications for clinical and translational efforts.

GENETIC ALTERATIONS IN LIVER CANCER

During the last decade, a detailed map of the structural variation in the human cancer genome has been generated.¹¹ This map reveals that tumor development is the consequence of intragenic mutations in approximately 140 genes belonging to 12 signaling pathways regulating three core cellular processes—cell fate, cell survival, and genome maintenance—that can promote or “drive” tumorigenesis in the majority of human cancers.¹¹ Hepatocarcinogenesis can, therefore, be considered a multistep process that is orchestrated by a sequence of epigenetic and genetic alterations leading to disruption in these core processes by the activation or inhibition of key downstream signaling such as p53, WNT, β -catenin, MYC, the ErbB family, as well as chromatin modifications.¹¹

Structural variation and chromosomal aberrations in tumors are traditionally regarded as evidence of gene deregulation and genome instability, and may facilitate the identification of crucial genes and regulatory pathways that are perturbed in diseases.¹² Large, genomewide association studies (GWAS) recently identified liver disease-specific susceptibility loci, including in HCC.^{13,14} Most of these studies employed powerful high-throughput microarray technology for single nucleotide polymorphism (SNP) genotyping and array-based comparative genomic hybridization (aCGH). These technologies enable a high-throughput analysis of DNA copy number and yield comprehensive information for determining the molecular pathogenesis of human HCC.

A meta-analysis of aCGH studies of chromosome aberrations in human HCC shows that specific chromosomal gains and losses correlate with etiology and histologic grade.¹⁵ In HCC, the most frequent amplifications of genomic material involve 1q (57.1%), 8q (46.6%), 6p (22.3%), and 17q (22.2%), whereas losses are most common in 8p (38%), 16q (35.9%), 4q (34.3%), 17p (32.1%), and 13q (26.2%). Deletions of 4q, 16q, 13q, and 8p correlate with HBV infection and a lack of HCV infection. Chromosomes 13q and 4q are significantly underrepresented in poorly differentiated HCC, and gains of 1q correlate with other high-frequency alterations.¹⁶ Amplifications and deletions often occur on chromosome arms at sites of oncogenes (e.g., MYC on 8q24) and tumor suppressor genes (e.g., RB1 on 13q14), as well as at several loci that contain genes with known and/or suspected oncogenic functions (e.g., FZD3, WISP1, SIAH-1, and AXIN2), all of which modulate the WNT signaling pathway. In these meta-analyses, etiology and poor differentiation of HCC correlated with specific genomic alterations. In preneoplastic dysplastic nodules (DN), amplifications are most frequent in 1q and 8q, whereas deletions occur in 8p, 17p, 5p, 13q, 14q, and 16q.¹⁶ A gain of 1q appears to be an early

event that develops in DN, possibly predisposing affected cells to acquire additional chromosomal aberrations.

A comprehensive collection of common aberrations from both human and rodent HCC is provided in the OncoDB.HCC database (<http://oncoadb.hcc.ibms.sinica.edu.tw>).¹⁷ This database provides a useful, validated, and graphic integration of published data derived from loss of heterozygosity (LOH) analyses, aCGH, gene expression microarrays, as well as proteomics, which is publically assessable for the validation of possible molecular targets.

Recently, a systematic strategy to identify potential driver genes by integrating whole genome copy number data with gene expression profiles of HCC patients was introduced.¹⁸ Using regional pattern recognition approaches, the authors discovered the most probable copy number-dependent regions and 50 potential driver genes. At each step of the process, the functional relevance of the selected genes was evaluated by estimating the prognostic significance of the selected genes. Further validation using small interference RNA-mediated knockdown experiments showed proof-of-principle evidence for the potential driver roles of the genes in HCC progression (i.e., *NCSTN*, *SCRIB*). In addition, the systemic prediction of drug responses using the Connectivity Map,¹⁹ a compendium of functional connections between drugs and genes, implicated the association of the 50 genes with specific signaling molecules associated with hepatocarcinogenesis (*mTOR*, *AMPK*, and *EGFR*). It was concluded that the application of an unbiased and integrative analysis of multidimensional genomic data sets can effectively screen for potential driver genes and provide novel mechanistic and clinical insight into the pathobiology of HCC.

In a similar approach, a recent study used an integrative approach combining information from high-resolution aCGH and gene expression profiling with clinical data from HCC patients to identify copy-number variations (CNV) in HCC with functional relevance for tumor progression.²⁰ The investigation was restricted to genes that showed (1) recurrent CNVs, (2) correlation of the CNVs and the transcriptome, and (3) a selective association to patients' outcomes to distinguish "drivers" from passengers. The authors were able to demonstrate significant differences in CNVs between patients with good and poor outcome and generated a 10-gene signature as a molecular predictor of patient survival and validated the signature in several independent cohorts. Both these studies elegantly illustrate the power of multilayer integrative analyses to identify the functional significance of genomic alterations in human HCC.

EPIGENETIC ALTERATIONS IN LIVER CANCER

Epigenetic alterations such as DNA methylation are important factors in tumor development for many cancers.²¹ Changes in DNA methylation patterns are believed to be early events in hepatocarcinogenesis, preceding allelic imbalances and ultimately leading to cancer progression, thereby adding considerable complexity to the pathogenesis of liver cancer.²²

Global hypomethylation and promoter hypermethylation in certain cancer-related genes are known drivers of hepatocarcinogenesis with an association to biologic behavior and prognosis.²³ Methylation patterns can further be used to classify patients according to different etiological factors (e.g. HBV, HCV, alcohol).^{24,25} Moreover, in addition to changes in global methylation patterns, distinct methylation patterns strongly correlate with clinical characteristics of HCC patients.²⁵ Methylation patterns in a 807 cancer-related gene panel could successfully separate primary HCC samples according to their biologic subtype.²⁶ Consistent with previous studies, patients with progenitor cell origin displayed the worst clinical outcome.²⁷ The confirmation of a multistep, epigenetic-driven sequence of molecular alteration in hepatocarcinogenesis could further be demonstrated in HBV-related liver cancers. A stepwise hypermethylation of CpG islands of nine well-

described genes was seen from cirrhotic nodules over dysplastic nodules (low and high grade) to early carcinoma (eHCC) and, finally, progressed HCC (pHCC).²⁸

More recently, integrative genome-wide methylation analyses have been applied to 71 human HCC patients.²⁹ The methylation data were combined with those from a microarray analysis of gene reexpression in four hepatoma cell lines following their exposure to DNA methylation inhibitors. A total of 13 candidate tumor suppressor genes were identified using this approach and, subsequently, *SMPD3* and *NEFH* were functionally validated as tumor suppressor genes in HCC. The authors could further show that *SMPD3* not only affects tumor aggressiveness, but also that reduced levels are an independent prognostic factor for early recurrence of HCC.

Although genetic changes in chromatin modulators are among the most common alterations in HCC (see the following), the role of epigenetic alterations beyond DNA methylation such as modification of histones (e.g., acetylation, methylation, phosphorylation, ubiquitylation, SUMOylation) are not well studied in HCC.³⁰ The fact that modifications of both repressing (e.g., H3 lysine 27 and histone H3 Lysine 9) and activating histone marks (e.g., H3 lysines 4) have a significant impact on the expression of critical genes associated with hepatocarcinogenesis highlight the need for whole genomic approaches such as chromatin immunoprecipitation with microarray technology (ChIP-chip) and ChIP sequencing (ChIP-seq) to address the role of these changes in a more global perspective.³¹

MicroRNAs are epigenetically active, small RNAs that are critically involved to regulate protein expression.³² Distinct microRNA expression patterns contribute to the definition of the cellular phenotype, including the regulation of proliferation, cell signaling, and apoptosis. Not surprisingly, the aberrant expression of microRNAs is associated with cancer initiation, propagation, and progression. Several microRNAs are frequently deregulated in HCC and associated with certain clinicopathologic features.³³ Several studies have demonstrated that microRNAs play an essential role in HCC progression by directly contributing to cell proliferation, apoptosis, and metastasis of HCC as well as by targeting a large number of critical protein-coding genes involved in hepatocarcinogenesis.³⁴ The profiling of microRNA expression by microarray revealed subclasses associated with clinicopathologic features as well as mutations in several oncogenic pathways such as β -catenin and *HNF1A*.³⁵ Furthermore, microRNA profiling of 89 HCC samples using a ligation-mediated amplification method revealed three distinct clusters HCCs reflecting the clinical behavior of the tumors as well as identifying the microRNAs family mir-517 with increased tumorigenicity of HCC cells.³⁶

Ji and colleagues³⁷ confirmed the therapeutic potential of microRNA-based treatment modalities in HCC. The authors demonstrated that miR-26 levels are associated with a response to adjuvant therapy with interferon α (IFN- α) and, more recently, developed a simple and reliable companion diagnostic (MIR26-DX) to select HCC patients for adjuvant IFN- α therapy as a first step to successfully translate information from large scale analyses into the clinics.³⁸

MUTATIONAL LANDSCAPE OF GENETIC ALTERATIONS IN HCC: THE NEXT GENERATION

Sophisticated next-generation sequencing (NGS) technologies are now applied in cancer research for complete and cost-efficient analyses of cancer genomes at a single nucleotide resolution and have advanced into valuable tools in translational medicine.¹² The implementation of NGS to solid tumors like HCC is challenging because the proportion of normal cells or the stromal composition within a given sample contributes to the genomic signature

and, therefore, may require additional coverage (i.e., read depth). Also, HCCs often arise in the background of a chronically diseased liver with underlying cirrhosis, fibrosis, or HBV or HCV infection, which may complicate the tumor/normal variant discovery when compared to the peritumoral liver tissue or even blood.³⁹ Therefore, the number of studies where NGS technologies—in particular, whole exome sequencing—have been applied to investigate HCC is, so far, limited and only conducted on a few patients.⁴⁰ However, all the studies revealed that the landscape of molecular alterations in HCC is relatively broad, with the number of mutations found ranging from 5 to 121 mutations per tumor. Thus, due to the genetic heterogeneity, a rather complex interaction of multiple mutations in the development of a singular HCC has to be assumed.^{41–44} Although no clear oncogenic addiction has been demonstrated, a high number of mutations in p53 and Wnt/ β -catenin signaling were detected (Fig. 51.1). Thus, results from in-depth analyses strengthen existing evidence that p53 and Wnt/ β -catenin signaling are among the most common molecular changes involved in HCC development. Another interesting finding is the high frequency of genetic alteration in genes involved in chromatin remodeling. Overall, 16% to 24% of HCCs showed genetic alterations in these pathways, thereby suggesting a causative association with hepatocyte transformation and highlighting recent evidence for the key role of epigenetics in hepatocarcinogenesis.⁴⁵

Two recent studies on whole exome/genome sequencing of 87 and 88 human HCCs as well as matched normal tissue^{46,47} con-

firmed the previous studies that β -catenin (10% and 15.9%) and TP53 (18% and 35.2%) are the most frequently mutated oncogene and tumor suppressor, respectively, in HCC.^{46,47} The study by Kan et al.⁴⁷ also detected several drugable mutations, including activating mutations of Janus kinase 1 (9.1%), which might provide an option for novel individualized therapeutic interventions. Interestingly, Nault et al.,⁴⁸ using traditional Sanger sequencing, identified somatic mutations activating telomerase reverse transcriptase as both the earliest and the most frequent mutations in human preneoplastic lesions (25%) as well as hepatocellular carcinomas (59%) and is associated with activating *CTNNB1* mutations.⁴⁸

Compared to whole-genome sequencing, the application of RNA sequencing in liver cancer is currently limited to three studies. One study investigated the transcriptomes of 10 matched HBV-related HCC cases, identifying a total of 1,378 differentially expressed genes with a specific enrichment of chromosome location on 8q21.3 to 24.3.⁴⁹ Another study investigated three paired nontumor and tumor specimens demonstrating that *ADAR1*-mediated *AZIN1* RNA editing is linked to tumor initiation and development in liver cancer.⁵⁰

Sequential molecular alterations during human hepatocarcinogenesis from dysplastic lesions to eHCC and, ultimately, pHCC are not clearly defined. This lack of information represents a major challenge in the clinical management of patients at risk. Although recent results associating *MYC* activation with early stages of malignant conversion into HCC, detailed molecular sequences that drive premalignant lesions into pHCC still remain

Figure 51.1 Major oncogenic pathways and genetic landscape in hepatocellular carcinoma (HCC). The scheme shows the major disrupted pathways in HCC patients (*outer circle*). The *inner circle* emphasizes the frequency of genetic alterations within the corresponding pathways and their putative contribution to hepatocarcinogenesis. Frequencies are based on results from recent whole genomic studies.^{41–44} Representative members of each pathway most frequently altered in HCC are also shown.

to be clarified.⁵¹ In the third study, integrative transcriptome sequencing to the tumor-free surrounding liver ($n = 7$), low-grade ($n = 4$) and high-grade dysplastic lesions ($n = 9$), eHCC ($n = 5$), and pHCC ($n = 3$) from eight HCC patients with HBV infections was applied.⁵² The results of the study indicate that molecular profiles of dysplastic lesions and eHCC are quite uniform. In contrast, a sharp increase in heterogeneity on both mRNA and DNA levels is observed in progressed HCC. These molecular alterations result in massive deregulation of key oncogenic molecules such as transforming growth factor beta 1 (TGF- β 1), MYC, PI3K/AKT, and suggest that activation of prognostically adverse signaling pathways is a late event during hepatocarcinogenesis (Fig. 51.2).

THE MICROENVIRONMENT OF LIVER CANCER

HCC develops on the basis of chronic liver disease and, in more than 80% of the cases, with preexisting liver cirrhosis. For a complete understanding of the molecular mechanisms of hepatocarcinogenesis, the underlying liver disease leading to a chronically altered inflamed liver microenvironment has to be appreciated.⁵³ Recent research efforts have focused on the identification of key factors that contribute to the disruption of the liver microenvironment and the generation of an adverse niche(s) that promotes he-

patocarcinogenesis. Among the most prominent factors involved in the so called inflammation-fibrosis-cancer axis is the nuclear factor kappa B (NF- κ B) pathway.⁵⁴ The dominant role of this pathway for hepatocarcinogenesis is well documented.⁵⁴ However, the absence of NF- κ B by genetic loss of the NF- κ B master regulator NEMO significantly enhanced liver cancer development in a mouse model, indicating that inhibition of NF- κ B may not only exert beneficial effects, but also may negatively impact hepatocyte viability, especially when NF- κ B inhibition is pronounced.⁵⁵

The importance of the microenvironment is further highlighted in a recent study demonstrating that transplantation of hepatic progenitor cells gave rise to cancer only when introduced into a liver with chronic damage and compensatory proliferation.⁵⁶ Interestingly, similar to observations made in human hepatocarcinogenesis, the cells resembling these progenitor cells quiescently resided within dysplastic lesions for several months before the appearance of HCC. During this time, the progenitor cells acquired autocrine interleukin (IL)-6 signaling that stimulated in vivo growth and malignant progression, which might be a general mechanism of progenitor cell-induced HCC.

However, the microenvironment does not only contribute to tumor initiation. Although gene-expression profiles of tumor tissue failed to yield a significant association with survival, a 186-gene signature generated from the surrounding nontumoral liver tissue was highly correlated with outcomes in a cohort of more than 300

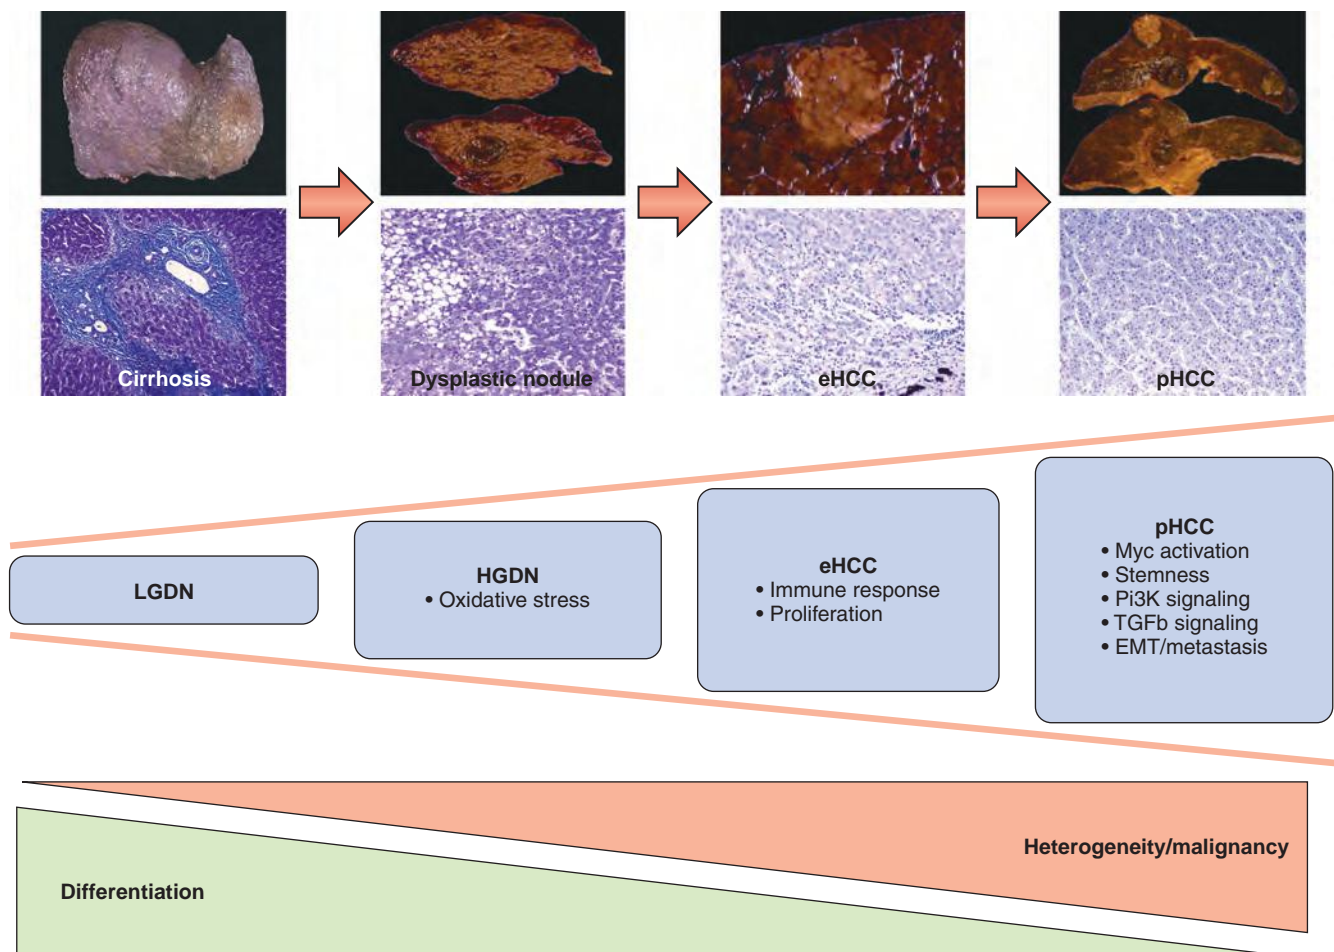

Figure 51.2 Sequential evolution of liver cancer. The current concept considers hepatocarcinogenesis as a multistep process that develops on the basis of a chronically altered microenvironment (i.e., cirrhosis) and progresses from dysplastic nodules (high grade and low grade) over early HCC to progressed HCC (*upper panels*). On the molecular level, the different stages are characterized by progressive activation of signaling pathways related to oxidative stress, immune response, and proliferation (*middle panel*). However, the activation of prognostically adverse signaling occurs late during the evolution of liver cancer. During this process, a progressive loss of differentiation with a concomitant acquisition of malignant and invasive properties is observed (*lower panel*). LGDN, low-grade dysplastic nodule; HGDN, high-grade dysplastic nodule; EMT, epithelial-mesenchymal transition.

HCC patients.⁵⁷ Consistently, this poor-prognosis signature contained gene sets associated with inflammation, such as IFN signaling, NF- κ B, and tumor necrosis factor α (TNF- α). Further, a gene set enrichment analysis showed that the downstream targets of IL-6 were strongly associated with the poor-prognosis signature, again confirming the importance of this signaling for hepatocarcinogenesis.

Together, these studies demonstrate the complexity of molecular mechanisms influencing the development and progression of liver cancer that are exerted by epigenetic and genetic alterations and a cross-talk between microenvironment and damaged hepatocytes and/or cancer cells, respectively.

CLASSIFICATION AND PROGNOSTIC PREDICTION OF HEPATOCELLULAR CARCINOMA

The application of microarray technologies to characterize tumors on the basis of global gene expression has had a significant impact on both basic and clinical oncology.¹⁰ The goal of tumor microarray studies generally includes the discovery of subsets of tumors (class discovery), which enables diagnostic classification (class comparison), a prediction of clinical outcome (class prediction), and mechanistic analysis. Verification and validation of the primary results are essential for the discovery of oncogenic pathways and the identification of therapeutic targets.⁸

The goal of all staging systems is to separate patients into homogeneous prognostic groups to permit the selection of the most appropriate surveillance as well as to find a specific therapy for each subtype. Although much work has been devoted to establishing prognostic models for HCC by using clinical information and pathologic classification, many issues still remain unresolved.⁵⁸ More than 20 studies on prognostic HCC gene expression profiling, as well as several reviews, have appeared during the last 10 years.⁴ However, results from these studies are quite heterogeneous and, besides disruption in general cancer-related processes such as proliferation, apoptosis, neoangiogenesis as well as prometastatic and proinflammatory gene sets, the overall similarity was low, thus limiting a successful implementation into clinical practice. A potential explanation is the fact that the interpretation of molecular profiling studies of HCC poses more challenges than other human tumors, mainly because of the complex pathogenesis of this cancer.⁵⁹ As already emphasized, HCC arises in diverse settings ranging from infection with HBV or HCV to chronic metabolic diseases as varied as diabetes, NAFLD, and hemochromatosis. These different disease stages represent complex assortments of genetic and epigenetic aberrations as well as altered molecular pathways.^{39,60}

A recent study aimed to generate a composite prognostic model by evaluating 22 prognostic gene expression signatures generated from tumors as well as cirrhotic tissues in a cohort of 287 patients with early stage HCC (BCLC 0/A).⁶¹ Overall, most previously reported signatures retained their prognostic ability in this independent data set. Out of these 22 signatures, 17 were able to adequately subclassify patients according to their prognostic trait. It is noteworthy that none of the signatures reflecting a progenitor cell origin (i.e., EpCAM, hepatoblastoma-C2, CK19-rat, CK19-human signature) could be confirmed to be of prognostic value. However, these signatures have not been generated for the classification of early stages of HCC.

Another important finding of this study was the observation that gene expression profiles obtained from paired biopsies from the center and periphery of the same tumor in 15 tumor specimens showed a high (>80%) transcriptomic concordance. Although these observations provide at least some evidence for stability of gene expression signatures in paired biopsies and suggests a low influence of sampling error, more in-depth analyses are needed to

better define the intratumoral genetic heterogeneity of HCC that is likely to contribute to the high tumor recurrence and chemoresistance of the disease.^{62,63}

Nault et al.⁶⁴ aimed to identifying a robust molecular signature to accurately predict the clinical outcome of HCC patients who underwent curative surgical resection. They identified a panel of five genes (*TAF9*, *RAMP3*, *HNI1*, *KRT19*, and *RAN*) in a training cohort of 314 HCC patients with a strong prognostic relevance and further validated this panel in two independent validation cohorts with different HCC etiologies.⁶⁴ The five-genes panel was associated with disease-specific survival both in the training and in the validation cohort, and was found to be significantly more accurate in predicting the patients' prognosis (i.e., survival and recurrence) when compared to known gene expression signatures. Due to the simplicity of the panel and its reproducibility in different technologies (i.e., gene expression microarray and real-time reverse-transcription polymerase chain reaction [qRT-PCR]), the work by Nault et al. has a high potential for implementation into the clinical management of HCC. In particular, the score may be helpful to stratify patients at high risk for relapse and tumor-related death before the decision of liver resection or transplantation is made. However, independent validation of this prognostic algorithm by different groups and independent cohorts is needed before the panel can be used for clinical decision making.

Two independent studies provide evidence that the oncofetal marker *SALL4* could be an attractive therapeutic target in HCC with progenitor cell origin.^{65,66} High *SALL4* expression was significantly associated with overall survival of patients in large independent cohorts. Further, and consistent with its oncofetal role, *SALL4* overexpressing tumors shared similar molecular profiles with fetal progenitor cells and stemness-associated HCC. Finally, by using RNAi and a specific inhibitory 12-AA peptide against *SALL4*, the authors could convincingly show that *SALL4* possessed therapeutic potential in HCC by interacting with *PTEN/PI3K-AKT* signaling via the interaction with the NuRD complex.⁶⁷ These studies confirm several recent observations indicating that HCCs harboring phenotypic features of stem/progenitor cells constitute a subclass of therapeutically challenged cancer patients that have a particularly poor prognosis.^{27,68,69}

Contrary to HCCs, the molecular pathology of intrahepatic cholangiocellular carcinoma (ICC) is less well investigated. Most of the studies on cholangiocarcinogenesis focused on the investigation of few candidate genes.⁷⁰ In a seminal work on both genomic and genetic features of ICC gene expression, profiles of 104 surgically resected cholangiocarcinoma samples were collected and analyzed from patients in Australia, Europe, and the United States.⁷¹ The authors discovered new two prognostic subclasses of patients defined by a 238-gene classifier as well as *KRAS* mutations and increased levels of *EGFR* and *HER2*, and concomitantly validated promising therapeutic strategies in different ICC cell lines, which resembled the different prognostic subtypes. Furthermore, this study also addressed the importance of the stromal component of ICC by laser capture microdissection of epithelial and stromal compartments from 23 tumors. Although the tumor epithelium was defined by deregulation of the *HER2* network and frequent overexpression of *EGFR*, *c-MET*, *pRPS6* as well as proliferation, the stroma was predominantly enriched for inflammatory gene sets. In another study, gene expression analyses of 149 patients with ICC from formalin-fixed paraffin-embedded samples were performed.⁷² A Gene Set Enrichment Analysis (GSEA) and functional characteristics of the patients again revealed two broad molecular subclasses—*proliferation* and *inflammation*—defined by the differential expression of 1,565 significant genes. The proliferation class was associated with aggressive tumor biology as well as a poor prognosis and was characterized by molecular enrichment of oncogenic pathways (e.g., *RAS/RAF/MAPK*, *VEGF*, and *PDGF*). The inflammation class displayed a better prognosis and enrichment of immune-related signaling, in particular IL-10 and signal transducer and activator of transcription 3 (*STAT3*)

signaling. Furthermore, a subgroup of ICCs in the proliferation class shared features of several previously published prognostic HCC signatures with a possible progenitor cell origin, which supported the hypothesis that these tumors may be derived from a common origin or precursor cell(s). This hypothesis is supported by recent work by Woo et al.,⁷³ which applied an integrative oncogenomic approach to address the clinical and functional implications of the overlapping phenotype of combined hepatocellular cholangiocarcinoma (CHC), a histopathologic intermediate between HCC and cholangiocellular carcinoma (CC).

CONCLUSION AND PERSPECTIVE

Next-generation technologies, in particular gene expression microarrays and, more recently, next-generation sequencing, have provided an extraordinary opportunity for integrative analyses of the cancer (epi-) genome as well as transcriptome. Array-based gene expression profiling not only has advanced our understanding of cancer biology, but also has begun to influence decision making in clinical oncology, which may ultimately allow for the development of more effective therapies. The power of gene expression profiling of HCC can be further enhanced by cross-comparison analyses of multiple gene expression data sets from human HCC and the rich database of HCC in animal models.^{74,75} The success

of these new analytical approaches, comparative and/or integrative functional genomics, suggests that integration of independent data sets will enhance our ability to identify robust predictive markers. Despite the success of these approaches in preclinical translational studies, the clinical application of gene expression profiling is still immature. Although current signatures accurately classify HCCs according to their natural biology, they are unable to predict the response to currently used therapies.⁵⁹ Furthermore, HCC with progenitor cell features display a particular aggressive behavior, which might indicate that tumor heterogeneity and resulting chemoresistance might be generated in molecularly plastic cancer stem cells (CSCs).⁷⁶ Because CSCs by definition are a rare subpopulation of cells, their molecular profile might be diluted by the bulk of tumor cells, which further hampers therapeutic progress.⁷⁷ However, based on the exciting results of recent studies and the advent of NGS technologies that offer unprecedented depths and resolution, it seems reasonable to predict that the genomic technologies will play an increasingly important role in clinical oncology. The immediate focus undoubtedly will be on incorporating these whole-genomic technologies into clinical trials. To achieve this ambitious goal, systematic and standardized collections of tissue specimens from HCC patients (e.g., mandatory biopsies) for subsequent prospective molecular analyses are urgently needed to ultimately improve the diagnosis and treatment of liver cancer patients.

52 Cancer of the Liver

Yuman Fong, Damian E. Dupuy, Mary Feng, and Ghassan Abou-Alfa

INTRODUCTION

Primary cancers of the liver represent the fifth most common malignancy worldwide and the second most common cause of death from cancer. This is due to the relationship of hepatocellular carcinoma to chronic hepatitis B virus (HBV) and hepatitis C virus (HCV) infections.¹ The prognosis of untreated hepatocellular carcinoma (HCC) has a dismal prognosis, with a 5-year survival rate below 10%.² The combination of cancer and chronic liver disease add significant complexity to treatment. The great progress in understanding the natural history, pathogenesis, and tumor biology of HCC has resulted in effective treatment options. For localized HCC, surgical resection and orthotopic liver transplantation (OLT) are the gold standard therapies. Formidable radiologic directed local and regional therapies, radiation therapy, and systemic therapies now round out a full arsenal of treatments even for disseminated disease. There have also been marked advances in therapies for hepatitis³ and in care of the associated liver parenchymal disease. However, this optimism may be negated by the continued lack of a true breakthrough in screening and early detection, and the continued rising incidence of HCC globally.

EPIDEMIOLOGY

The annual number of worldwide liver cancer cases (748,300) closely resembles the number of deaths (695,900). Long-term survival rates are 3% to 5% in most cancer registries. In the United States, approximately 30,640 new tumors of the liver and intrahepatic bile ducts are diagnosed each year, with 21,670 deaths estimated annually.¹ HCC is 2.3 times more common in men than in women, and this difference is consistent globally. Androgen and androgen receptor (AR) have long been implicated in this male-dominance feature.⁴ In the United States, rates of HCC are two times higher in Asians than African Americans, which are two times higher than those in Caucasians. There has been a significant overall increase in the incidence of HCC in the United States during the past 25 years.⁵ This parallels the increase in HCV infection, the increase in immigrants from HBV-endemic countries, and an increase in nonalcoholic fatty liver disease. The widespread utilization of HBV vaccination is leading to a decrease in liver cancer in some areas. A dramatic demonstration of this is available from Taiwan, where an HBV vaccine was introduced in 1984, and a reduction of liver cancer was observed in children from 0.54 per 100,000 to 0.2 per 100,000 during a 16-year period.⁶

ETIOLOGIC FACTORS

Viral Hepatitis and Hepatocellular Carcinoma

The variable geographic incidence of liver cancer⁷ reflects the variable geographic incidence in HCV and HBV infections, which

account for 75% of the world's cases. Both case control studies and cohort studies have shown a strong association between chronic hepatitis B carriage rates and increased incidence of HCC. Beasley et al.⁸ followed Taiwanese male postal carriers who were hepatitis B surface antigen (HBsAg)-positive and found an annual HCC incidence of 495 per 100,000. This represented a 98-fold greater risk than observed in HBsAg-negative individuals. By evaluating apparently asymptomatic HBsAg-positive blood donors at American Red Cross centers, a relative risk of 12.7 was noted for liver cancer compared with HBsAg-negative individuals. A multivariate analysis has been used to determine *risk scores* for the development of HCC.⁹ Factors predictive of HCC include male gender, advanced age, specific promoter mutations, the presence of cirrhosis, and higher viremia levels. If validated, this may improve patient selection for surveillance.

The exact mechanism by which HBV infection causes HCC is not known.^{10,11} Some have postulated that the effect of HBV on hepatic carcinogenesis is indirect, through the process of inflammation, regeneration, and fibrosis associated with chronic hepatitis and cirrhosis. Consistent with this hypothesis, 70% of cases of HBV-related HCC occur in association with cirrhosis. It is well known that cirrhosis of all causes may result in HCC.

There is evidence that the effect may be a direct viral effect. HBV DNA may become integrated within the chromosomes of infected hepatocytes, and in some HCCs, this integration of viral genetic material may occur in a critical location within the cellular genome. For example, integration of HBV DNA has been observed within the retinoic acid receptor alpha gene and within the human cyclin A gene, both of which play crucial roles in cellular growth. However, in most cases, the HBV DNA integration appears to be random. The hepatitis B x gene (*HBx*) product has been implicated in causing HCC because it is a transcriptional activator of various cellular genes associated with growth control. *HBx* has been found to interact with *p53*, interfering with its function as a tumor suppressor.

HCV is an RNA virus without a DNA intermediate form, and therefore, cannot integrate into hepatocyte DNA. In contrast to HBV, HCV is more likely to lead to chronic infection (10% versus 60% to 80%), and cirrhosis (20-fold increase).¹² The typical interval between HCV-associated transfusion and subsequent HCC is only about 30 years (compared with 40 to 50 years for HBV). The state of the liver also differs in that HCV-associated HCC patients tend to have more frequent and more advanced cirrhosis. In HBV-associated HCC, only half the patients have cirrhosis. The risk of developing HCC in a patient with HCV-related cirrhosis is 5% per year versus 0.5% per year for HBV-related cirrhosis.

There have been extensive efforts to establish the molecular pathways involved in the pathogenesis of HCC.^{13,14} Some of the abnormalities that are commonly found in HCC include (1) cell-cycle dysregulation associated with somatic mutations or loss of heterozygosity in *TP53*, silencing of *CDKN2A* or *RB1*, or *CCND1* overexpression; (2) increased angiogenesis accompanied by overexpression or amplification of *VEGF*, *PDGF*, and *ANGPT2*; (3) evasion of apoptosis as a result of activation of survival signals such as nuclear factor kappa B (NF- κ B); and (4) reactivation of *TERT*.

There is emerging evidence of the importance of microRNAs and epigenetic alterations such as hypermethylation in the pathogenesis of HCC. MicroRNA-155 (miR-155) levels were significantly increased in patients infected with HCV, and overexpression of miR-155 was associated with nuclear accumulation of beta-catenin by increased Wnt signaling, thereby implicating this pathway in HCV-associated hepatocellular carcinogenesis.¹⁵

Alcohol-Induced Hepatocarcinogenesis

There is a strong association between alcoholic cirrhosis and the development of HCC. By itself, chronic alcohol consumption has carcinogenic effects. Thus, chronic alcohol intake is known to lead to oxidative stress in the liver, inflammation, and cirrhosis. Ethanol is metabolized by alcohol dehydrogenases and cytochrome P-450, producing acetaldehyde and reactive oxygen species. Acetaldehyde binds directly to proteins and DNA. It damages mitochondria, initiating apoptosis. P-450 metabolism leads to reactive oxygen species, which lead to lipid consumption peroxidation, protein oxidation, and DNA adducts.¹⁶ Alcohol leads to monocyte activation and inflammatory cytokine production. Oxidative stress has been demonstrated in alcoholic cirrhosis through increased isoprostane, a marker of lipid peroxidation.¹⁷ Oxidative stress promotes the development of fibrosis and cirrhosis, creating a permissive HCC microenvironment. Oxidative stress may also lead to decreased Signal Transducers and Activators of Transcription 1 (STAT1)-directed activation of interferon gamma (IFN γ) signaling with consequent hepatocyte damage.¹⁸

Nonalcoholic Fatty Liver Disease

HCC has been linked to nonalcoholic fatty liver disease (NAFLD). NAFLD is present in 30% of the general adult population, in 90% of morbidly obese adults (body mass index [BMI] ≥ 40 kg/m²), and in close to 74% of those with diabetes.¹⁹⁻²¹ The risk of HCC due to NAFLD appears to be less than that of chronic hepatitis C. A recent US study reported a 2.6% yearly cumulative incidence of HCC in NAFLD and 4% in HCV cirrhosis.²² Similarly, a prospective 5-year study from Japan reported a rate of HCC of 11.3% among patients with NAFLD cirrhosis compared to 30.5% among those with HCV-associated cirrhosis.²³ A recent study from Germany identified non-alcoholic steatohepatitis (NASH) as the most common etiology of HCC (24%), surpassing chronic hepatitis C (23.3%), chronic hepatitis B (19.3%), and alcoholic liver disease (12.7%).²⁴

Diabetes and obesity have been established as independent risk factors for HCC, and that association holds true in the setting of NAFLD and associated NASH.^{25,26} However, there is also increasing evidence suggesting that NAFLD contributes to noncirrhotic HCC, and that HCC can develop in patients with metabolic syndrome and NAFLD in the absence of NASH and fibrosis.²⁷

Other Etiologic Considerations

In addition to alcoholic cirrhosis and viral hepatitis, several underlying conditions have been found to be associated with an increased risk for the development of HCC (Table 52.1). These include autoimmune chronic active hepatitis, cryptogenic cirrhosis, and metabolic diseases. Metabolic diseases include hemochromatosis (iron accumulation), Wilson disease (copper accumulation), α_1 -antitrypsin deficiency, tyrosinemia, porphyria cutanea tarda, glycogenesis types 1 and 3, citrullinemia, and orotic acid urea. In children, congenital cholestatic syndrome (Alagille syndrome) is associated with a familial type of HCC.

Chemical Carcinogens

Probably the best-studied and most potent ubiquitous natural chemical carcinogen is a product of the *Aspergillus* fungus,

TABLE 52.1

Conditions Associated with Human Hepatocellular Carcinoma

Condition	Risk
<i>Cirrhosis</i>	
Hepatitis B virus	High
Hepatitis C virus	High

<i>Environmental</i>	
Thorotrast	Moderate
Androgenic steroids	Moderate
Cigarette smoking	Low to moderate
Aflatoxin	Moderate

called aflatoxin B₁.²⁸ *Aspergillus flavus* mold and aflatoxin product can be found in a variety of stored grains, particularly in hot, humid parts of the world, where grains such as rice are stored in unrefrigerated conditions. In the months following the monsoons in Southeast Asia, most village-based grains can be seen to be covered by a white layer of aflatoxin that is consumed with the grain. Data on aflatoxin contamination of foodstuffs correlate well with incidence rates of HCC in Africa and to some extent in China.

There is considerable literature on the hepatocarcinogenicity of anabolic steroids as well as the induction of benign adenomas by estrogens.²⁹ Although estrogens are capable of causing HCC in rodents, an epidemiologic association in humans has never been clearly shown. In an industrial society, a large number of environmental pollutants, particularly pesticides and insecticides, are known rodent hepatic carcinogens. In a recent case-control study, cumulative lifetime tobacco use of more than 11,000 packs and Asian ethnicity were independent predictors of HCC development amongst a cohort of patients with chronic liver disease, including HCV.³⁰

STAGING

Multiple clinical staging systems for hepatic tumors have been described. The most widely used is the American Joint Committee on Cancer/tumor-node-metastasis (AJCC/TNM) (Table 52.2).³¹ Adverse prognostic features include large size, multiple tumors, vascular invasion, and lymph node spread. Macroscopic or microscopic vascular invasions, in particular, have profound effects on prognosis. Stage III disease contains a mixture of lymph node–positive and –negative tumors. Stage III patients with positive lymph node or stage IV disease have a poor prognosis, and few patients survive 1 year.

The prognosis in patients with HCC is very much influenced by the presence and severity of underlying liver disease as well. The Child-Pugh scoring system is the most commonly used tool for assessing cirrhosis (see Table 52.2).³² It encompasses five parameters—bilirubin, albumin, prothrombin time, clinical ascites, and clinical encephalopathy—each of which is scored from one to three depending on severity. The key limitation of the Child-Pugh scoring system is its lack of any parameters pertaining to the cancer itself. Despite that, it remains incorporated into many HCC clinical trials as a tool to measure the extent of liver disease in the study populations, and thus, its use may not fade away any time soon. However, this main limitation of the Child-Pugh scoring system has been overcome by other scoring systems. Among those, the first to be established is the Okuda staging system. The

Cancer of the Liver Italian Program (CLIP) score was defined and studied prospectively in patients with HCC mainly caused by HCV.^{33,34} The CLIP score consists of the Child-Pugh score parameters combined with a subjective assessment of tumor in the liver, the presence or absence of portal vein thrombosis, and the alpha-fetoprotein (AFP) level. The addition of vascular endothelial growth factor levels to the CLIP parameters (V-CLIP) has been shown to provide a significantly more precise prognosis, but has yet to be prospectively validated.³⁵ The Chinese University Prognostic Index (CUPI) scoring system was developed in patients with mainly HBV-related HCC.³⁶ The CUPI parameters are bilirubin, ascites, AFP, alkaline phosphatase, the tumor extent (AJCC/TNM 5th edition), and clinical symptoms at presentation. A French system called the Groupe d'Etude et de Traitement du Carcinoma Hepatocellulaire (GETCH) staging system consists of bilirubin, Karnofsky performance score, AFP, alkaline phosphatase, and portal vein thrombosis.³⁷ Another scoring system that is mainly used in Japan is the Japan Integrated Staging (JIS) score.³⁸

Another commonly used scoring system is the Barcelona Clinic Liver Cancer (BCLC) classification system.³⁹ The BCLC couples prognosis with treatment assignment and has been validated prospectively.⁴⁰ However, it has been shown to be less valuable in the setting of more advanced disease, defined as BCLC category C.^{41,42} In retrospective analyses of patients with advanced-stage HCC seen by medical oncologists, the CLIP scoring system was noted to be the most informative regarding the outcome of this specific patient population.

DIAGNOSIS

The tests used to diagnose HCC include radiologic studies and pathologic diagnosis with biopsy. Core biopsies are most preferred because of the tissue architecture given by this technique. For patients suspected of having portal vein involvement, a core biopsy of the portal vein may be performed.⁴³ Morphologic features, such as stromal invasion, help distinguish high-grade dysplastic nodules from HCC.⁴⁴

The American Association for the Study of Liver Diseases (AASLD),⁴⁵ and the European Association for the Study of the Liver (EASL)⁴⁶ have outlined noninvasive criteria for the diagnosis of HCC. EASL recommends that lesions that are greater than 2 cm with characteristic radiologic features of arterial hyperenhancement on two different imaging modalities, or on one imaging modality alongside with a serum AFP of 400 ng/dL or more, are diagnostic of HCC, and no biopsy is needed. The AASLD added venous washout as a requisite radiologic feature. Detection of a lesion larger than 2 cm that exhibits both arterial hyperenhancement and venous washout in a single imaging modality concomitant with an AFP >200 ng/mL is sufficient to diagnose HCC.⁴⁷ Bialecki et al.⁴⁸ found a sensitivity and specificity of 89.1% and 100%, respectively, for liver biopsy compared to 64.9% and 62.8%, respectively, for the noninvasive EASL criteria. The fear of

biopsy-related hemorrhage is dissuaded by a 0.4% rate, and tumor seeding occurs at a low rate of 1.6%. When seeding does occur, it can be treated by local resection and is seldom a cause of morbidity and mortality.^{49,50}

TREATMENT OF HEPATOCELLULAR CARCINOMA

Many treatment options for HCC are available (Table 52.3). Resection and liver transplantation represent the potentially curative options with the longest track record. For small tumors, ablation and radiotherapy (RT) are quite effective and may be curative.

Surgical Resection for Hepatocellular Carcinoma

Patient Selection

Liver resection is the preferred treatment for the noncirrhotic patient with HCC. These patients generally have normal liver function, no portal hypertension, and can tolerate major liver resections with acceptable morbidity and low mortality. The selection of noncirrhotic patients with HCC for resection is as for other malignant lesions. Resection should be considered for patients where a complete resection of tumor is possible while preserving greater than 30% functional liver. If the potential remnant liver volume may be less than 30%, portal vein embolization is now a well-accepted preoperative preparatory method for increasing the potential remnant liver volume and safety of the resection.⁵¹

For cirrhotic patients, the primary determinant of outcome and selection of therapy is the degree of hepatic dysfunction and portal hypertension. Traditionally, only compensated cirrhotics

(Child-Turcotte-Pugh class A) were candidates for hepatic resection, whereas patients with significant hepatic functional dysfunction (Child class B or C) are generally not selected for resection because of poor outcome.⁵¹ Portal hypertension can be indirectly assessed clinically by the presence of splenomegaly, esophagogastric varices, and thrombocytopenia (platelet count $<100,000/\text{mm}^3$) or directly determined by hepatic venous wedge pressures (≥ 10 mmHg). With recent advances in perioperative care, there is growing evidence that liver resection for HCC in well-selected patients with mild portal hypertension is safe and can achieve a comparable outcome as in patients without portal hypertension.^{52,53}

The future remnant liver mass is another important factor to be considered in cirrhotic patients before resection. A too small remnant liver volume is associated with an increased risk for postresectional liver failure.⁵⁴ There is a general consensus that the critical remnant liver volume in cirrhotic patients is 50%,⁵⁵ and portal vein embolization should be considered if the future remnant liver volume is expected to be below 50%.⁵⁶⁻⁵⁹ Some investigators have even attempted to sequentially employ transarterial chemoembolization (TACE) to control the tumor or portal vein embolization (PVE) to increase residual liver volume, followed by definitive surgical resection.^{56,57} The sequential use of TACE and PVE results in more efficient hypertrophy of the future remnant liver compared to PVE alone.⁵¹

In other parts of the world, dynamic liver function tests are also employed for the assessment of suitability for liver resection. These include the indocyanine green (ICG) test and technetium-99m diethylenetriaminepentaacetic acid-galactosyl human serum albumin (technetium-99m galactosyl human serum albumin [99mTc-GSA] scintigraphy).^{51,55} An ICG retention rate of less than 14% proved to be a safe indicator for major hepatectomy in cirrhotic patients, whereas retention rates above 20% are considered a contraindication for major hepatectomy.⁶⁰⁻⁶²

Patient medical comorbidities considered are similar to an assessment for any major surgery. Some studies have reported age and gender to be independent risk factors for poor outcome after resection of HCC.⁶³ Other studies indicate that advanced age is more a surrogate for medical fitness, and that, with careful patient selection, elderly patients benefit as much from resection as younger patients.⁶⁴ Comorbidities as represented by American Society of Anesthesia (ASA) grade have been shown to correlate with survival.⁶⁵

^a Sorafenib is the only systemic therapy with level 1 evidence, proving a survival benefit.

Outcomes of Resection and Prognostic Factors

With improving patient selection and perioperative care, the outcome of hepatic resection for HCC has been continuously improved during the past 2 decades. Many large series of the past 10 years show that resection is associated with a perioperative mortality rate of less than 7%, and patients achieve an overall survival rate of 30% to 50% (Table 52.4).⁶⁵⁻⁷⁵ Many major centers are recently reporting operative mortalities less than 2%,^{68,70,74} even in cirrhotic patients.

Tumor factors most important for outcome are TNM staging at presentation, macro- and microvascular invasion, and the number of tumors. Large HCC has a propensity for vascular invasion and growth of tumor intraluminally. This is associated with intrahepatic satellite metastases via the portal venous system and is frequently associated with small satellite tumors. Intraluminal spread through the hepatic veins leads to pulmonary metastases.

One surgical factor prognostic for outcome is surgical margins. There is no clear margin size that has been universally agreed upon, but there is consensus on importance of an R0 resection.⁷⁶ Most surgeons prefer at least a 1-cm margin. In one 225 patient study, a 1-cm margin was associated with a 77% 3-year survival versus 21% for those with less than a 1-cm margin.⁷² It must be noted that in a randomized controlled trial, a 2-cm margin was associated with a decrease in recurrence as well as improved survival.⁷⁷ Studies have demonstrated improved outcome for anatomic versus nonanatomic resections for HCC.⁷⁸ In a series of 210 patients, 5-year survival rates were 66% for anatomic versus 35% in

nonanatomic resections.⁷² For small solitary tumors, anatomic resections seem to be less important.⁷⁹ Choice of margin and the anatomic approach for cancer clearance must be weighed against better perioperative outcome for limited parenchymal resection in cirrhotic patients.

Liver Transplantation for Hepatocellular Carcinoma

Patient Selection

Theoretically, liver transplantation is the ideal therapy for HCC in cirrhotic patients because it treats both the cancer as well as the underlying parenchymal disease. However, early experience with transplants produced dismal results. Bismuth et al.⁸⁰ was one of the first groups to consider that, in advanced disease, the likelihood of systemic disease was so high that recurrence rates, and therefore long-term outcomes, were unacceptably poor. They demonstrated that patients with limited disease (uninodular or binodular <3 cm tumors) had much better outcomes with transplant than resection (83% 5-year survival versus 18%).⁸⁰

The landmark works of Mazzaferro et al.⁸¹ have defined the most commonly used criteria for the selection of patients with HCC for transplantation. In their paper they defined the Milan criteria for transplantation as a single tumor less than 5 cm or three or fewer tumors all individually less than 3 cm (Fig. 52.1). Using these criteria for selection, patients transplanted had a very favorable outcome, including a 4-year actuarial survival rate of 85% and a recurrence-free survival rate of 92%. The suitability of these criteria for the selection of patients for transplant has been confirmed by numerous studies (Table 52.5).^{81–94}

The excellent outcomes of HCC patients within the Milan criteria led many to explore more expansive and inclusive criteria.⁹⁰ The most accepted of the expanded criteria is that from the University of California San Francisco (UCSF) group. They reported excellent results after transplant for solitary tumor \leq 6.5 cm, three or fewer nodules with the largest \leq 4.5 cm, and total tumor diameter \leq 8 cm (see Fig. 52.1). The UCSF criteria was associated with a survival of 90% and 75% at 1 and 5 years, respectively.^{90,95}

The largest experience to date using transplantation for HCC was reported from the University of California, Los Angeles

(UCLA).⁹⁶ In this study of 467 transplants performed for HCC, the overall 1-, 3-, and 5-year survivals were 82%, 65%, and 52%, respectively. Transplanted patients with tumors beyond the UCSF criteria had a survival below 50%.

Living Donor Liver Transplant

Because of the shortage of cadaveric livers, living donor liver transplant (LDLT) has become an increasingly utilized modality for the treatment of patients with decompensated cirrhosis. In many Asian countries, where prevalence of HCC is high, living related transplants are the most common liver transplants performed. Survival

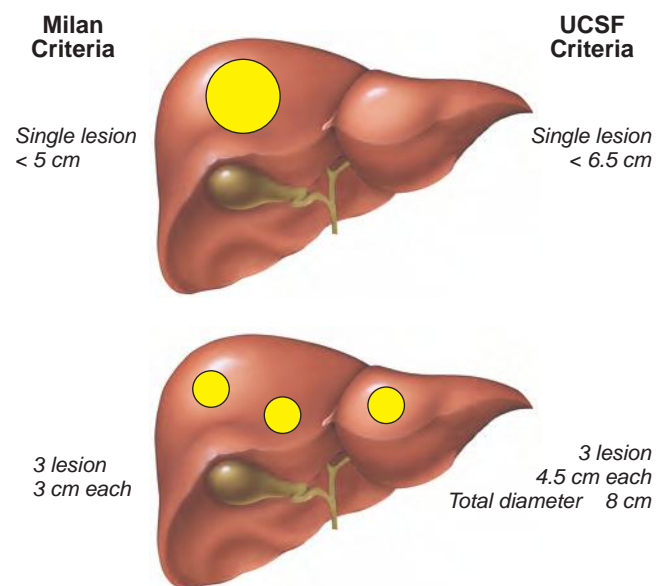

Figure 52.1 Milan (single lesion \leq 5 cm, or no more than 3 lesions \leq 3 cm) and University of California, San Francisco (UCSF) criteria (single lesion \leq 6.5 cm, or no more than 3 lesions \leq 4.5 cm and a total diameter of 8 cm) for patients with HCC and who are undergoing liver transplantation.

outcomes for all patients undergoing LDLT are comparable to the results with deceased donors (Table 52.6).^{97–102} The disadvantage is clearly the risk to the living donor, with morbidity as high as 40% and a 0.5% mortality. The greatest concern is that LDLT may encourage transplants for patients with unfavorable biology (outside of the established Milan or UCSF criteria) and pose unjustified risk to two lives, including the healthy individual.

Multimodality Management While Awaiting Transplant

To qualify for the wait list, a biopsy or one of the following criteria must be fulfilled: AFP >200 mg/mL, arteriogram confirming the tumor or arterial enhancement followed by portal venous wash-out on computed tomography (CT) scans or magnetic resonance imaging (MRI), or a history of local–regional treatment. Patients should be assessed radiologically for number and size of tumors, to rule out extrahepatic disease and vascular involvement. Patients with tumors less than 2 cm in size or patients who do not qualify for the Milan criteria can be listed for transplant, but they will receive no additional priority points for the tumor. The tumor should

be assessed every 3 months by CT scans or MRI to rule out progression of disease beyond the established criteria.

To reduce the likelihood of tumor progression while on the wait list, many local treatments are used, including TACE, percutaneous radiofrequency ablation (RFA), or percutaneous ethanol injection (PEI). TACE involves selective embolization of the arterial feeding vessels for the hepatoma with occlusive particles with or without admixed chemotherapeutic agents. TACE limits wait list dropout, decreases posttransplant recurrence, and can downstage HCC that is beyond transplant criteria.¹⁰³ A dropout rate of 14% was found in a series of patients treated with TACE as bridge to transplant, which compared very favorably to a dropout rate of 38% for an untreated group of patients reported by the Barcelona Liver Cancer study group.^{104,105}

For small, solitary tumor, PEI¹⁰⁶ or RFA can be effective treatment options for use as a bridge to transplant. In a series of 52 patients treated with RFA, the dropout rate was 6% at 12 months due to tumor progression with a 3-year disease-free survival of 76% for the 41 patients eventually transplanted.¹⁰⁷ Mazzaferro et al.¹⁰⁸ reported no dropout for their patients treated with RFA as bridge to transplant, with a 3-year survival of 83%.

ADJUVANT AND NEOADJUVANT THERAPY

Adjuvant Therapy

A recent report of a randomized trial of adjuvant IFN α -2b described an improved 5-year survival in patients with stage III/IVA tumor from 24% to 68% ($p = 0.038$).¹⁰⁹ In a separate, larger study, IFN α -2b therapy was not associated with reducing postoperative recurrence in a population at risk for viral hepatitis-induced hepatocellular carcinoma. In this study of 268 patients, the median recurrence-free survival was 42.2 and 48.6 months with observation and IFN α -2b therapy, respectively ($p = 0.828$).¹¹⁰

Another approach that has been evaluated is intrahepatic ¹³¹I-lipiodol. In a randomized study of 43 patients, adjuvant ¹³¹I-lipiodol administered via the hepatic artery was compared with observation after resection of HCC. There was an improvement in median disease-free survival noted in favor of the ¹³¹I-lipiodol arm (57.2 versus 13.6 months; $p = 0.037$).¹¹¹ However, a long-term follow-up of this trial at 10 years failed to show the same survival advantage.¹¹²

The best-studied systemic adjuvant therapy so far is acyclic retinoid, which was evaluated against placebo following surgical resection in 89 patients.¹¹³ Patients who received acyclic retinoid had a recurrence rate of 27% compared with 49% for patients who received placebo ($p = 0.04$) after a median follow-up period of 38 months. The prevention of second primary HCC was more marked after a median follow-up of 62 months ($p = 0.002$, log rank test), but the difference in survival rates did not reach significance until after 6 years, with an estimated 6-year survival of 74% versus 46%, respectively ($p = 0.04$).¹¹⁴

Sorafenib, which will be discussed at length in the Systemic Therapy section, was also studied in the adjuvant setting. In a pilot study of 31 patients with HCC who had undergone curative resection and were at high risk of recurrence, sorafenib prolonged the time to recurrence (21.5 versus 13.4 months; $p = 0.006$) and significantly lowered recurrence rate (29.4% versus 70.7%; $p = 0.006$).¹¹⁵ A currently fully accrued yet not reported phase III trial (STORM) randomized patients to adjuvant sorafenib versus placebo after surgery, radiofrequency ablation, or percutaneous alcohol injection with a primary end point of recurrence-free survival (Clinical Trial: NCT00692770). A phase II randomized, placebo-controlled study evaluating whether adjuvant sorafenib can prevent recurrence of HCC in high-risk orthotopic liver transplant recipients is currently enrolling (Clinical Trial: NCT01624285).

Neoadjuvant Therapy

Two randomized controlled trials and seven nonrandomized trials have evaluated preoperative transarterial chemotherapy. No clear advantage in disease-free or overall survival was found in these studies.^{116–118} Postoperative transarterial chemotherapy has been examined in four randomized controlled trials and three nonrandomized controlled trials. A meta-analysis of these trials revealed a significant improvement in disease-free and overall survival.¹¹⁷ The regimens consisted of Lipiodol and chemotherapy agents, including doxorubicin, mitomycin, and cisplatin. An analysis of postoperative adjuvant systemic chemotherapy trials demonstrated no consistent advantage in terms of disease-free or overall survival.^{113,119–122}

A combination regimen of systemic therapy that has been studied extensively in advanced HCC provided input for its potential use in the neoadjuvant setting. PIAF (cisplatin, IFN α -2b, doxorubicin, and 5-fluorouracil) have shown in a phase II study a response rate of 26% with a median survival of approximately 9 months.¹²³ Of the 13 patients (26%) who had a partial response, 9 underwent surgery and 4 (9%) achieved a complete pathologic response to chemotherapy. These results illustrated that chemotherapy for HCC is effective in selected patients and suggest the

possible use of PIAF as neoadjuvant therapy for medically fit patients with good liver function in whom cytoreduction might permit future resectability. The potential for cure would justify the risk of the significant toxicity profile of PIAF.

Choice of Resection, Ablation, or Transplantation

Although liver resection versus liver transplantation as primary therapy for patients with small HCC and adequate hepatic reserve is hotly debated, in most cases resection and OLT are complementary and not competing therapies. A number of studies report comparable overall survival rates for primary resection and primary OLT for transplantable HCC (Table 52.7).^{89,124–134}

Patients with limited disease have potentially curative treatment options. There is general consensus that in patients with no underlying liver dysfunction, limited disease should be resected because this gives the best chance of cure without an ongoing need of immunosuppression dictated by transplantation. The outcomes of resection are quite good, with 5-year survivals of 30% to 50% (see Table 52.4).

For patients with end-stage liver disease (ESLD) and limited HCC, OLT is currently the best treatment modality. However, OLT can only be offered only to a small proportion of patients due to donor organ shortage. Therefore, liver resection remains the most important surgical therapy in patients with HCC and well-preserved liver function (Child class A).⁵¹ Using resection as first-line therapy with salvage transplantation saved for recurrence is a common approach, especially for geographic regions with a high incidence of HCC and a low liver donation rate.^{135,136} Resection can, therefore, be used as bridge therapy before OLT to control the tumor burden in patients who fulfill the Milan⁸¹ or UCSF⁹⁰ criteria. In a study from a large Asian transplant center, the majority of patients (79%) who developed tumor recurrence after resection of small HCC were still eligible for salvage transplantation.¹³⁷ Primary resection also allows the opportunity to pathologically assess the tumor and adjacent liver tissue.¹³⁶ Pathologic prognostic factors such as micro- or macrovascular invasion, satellitosis, or occult tumors can be used as selection criteria for salvage liver transplantation in the case of recurrent tumor disease.

Patients with large HCC beyond the Milan or UCSF criteria have a less favorable outcome than those with small HCC.^{81,90} Patients in the United States outside the accepted criteria can be transplanted based on the physiologic Model for End-Stage Liver Disease (MELD) score but do not receive any exception points for HCC. In an analysis of 94 patients with HCC exceeding the Milan criteria, results of resection was compared to OLT.¹³⁸ The overall survival rate was 66% for both groups even though the mean tumor size was 10 cm for the resection group and 6.4 cm for the OLT group. The results suggest that resection and OLT in patients with HCC beyond the Milan criteria have similar outcomes. A proposed algorithm of care from the Barcelona Clinic is shown in Figure 52.2.

Ablative Therapy For Localized Hepatocellular Cancer

Chemical Ablation

Chemicals destroy tumor tissue by direct dehydration of the cytoplasm, protein denaturation, and consequent coagulation necrosis as well as from indirect ischemia from vascular thrombosis from endothelial damage.^{139,140} The direct instillation of chemicals such as absolute ethanol or acetic acid has been long studied for the treatment of HCC.^{141–143} Chemical ablation is very inexpensive and, therefore, it is more widely used in developing countries with a high incidence of HCC. Intratumoral instillation of acetic acid for the treatment of HCC compares favorably

with that of ethanol treatment.^{144,145} Moderate quality evidence supports that RFA is superior to chemical ablation for the treatment of HCC.¹⁴⁶ Chemical ablation requires multiple applications, and thus, thermal ablation has largely replaced chemical ablation in many cases. In certain anatomic locations, such as adjacent to the major biliary tree or gallbladder, the combination of thermal ablation and ethanol ablation has shown some benefit.^{147,148}

Radiofrequency Ablation

RFA is currently the most widely used ablative technique for the treatment of liver malignancies. The term *radiofrequency* applies to all electromagnetic energy sources with frequencies less than 30 MHz, although most clinically available devices function in the 375 to 500 kHz range. The technique for thermal ablation in the liver by using RFA was first described in animal liver models in 1990^{149,150} and was later reported in a patient in 1995.¹⁵¹

In this technique, the RF electrode is placed into the tumor with imaging guidance. The electrode is coupled to an RF generator and is grounded by means of a grounding pad or pads applied to the thighs. The RF generator produces a voltage between the active electrode (applicator) and the reference electrode (grounding pad), establishing electric field lines that oscillate with the alternating current. This oscillating electric field causes electron collisions with the adjacent molecules closest to the applicator, inducing frictional heating.¹⁵² Tissue heating to temperatures greater than 60°C leads to immediate cell death. Thus, for any given RFA procedure, the application of energy from the applicator is maximized to create a zone of tissue necrosis that encompasses the tumor and a margin of normal parenchyma.¹⁵³ The volume of ablation achieved is based

on the energy balance between heat conduction of the local RF energy applied and heat convection from the circulating blood and extracellular fluid.

In the United States, there are three commercially available percutaneous RFA systems (Fig. 52.3). Two of the systems (Boston Scientific/RadioTherapeutics and RITA Medical Systems) use a deployable RF array electrode that consists of 4 to 16 small wires (tines) deployed through a 14- to 17-G needle. Because the tines of the Boston Scientific device (LeVeen electrode) curve back toward the handle (see Fig. 52.3), the array is initially deployed in the deep portion of the tumor. In contrast, the RITA electrode tines course forward and laterally so the probe is deployed on the near surface of the tumor. The LeVeen electrode measures impedance only, and treatment time depends on repeated increases in impedance during active heating, which is a measure of tissue desiccation indicative of adequate thermocoagulation. With the RITA system, temperature readings are obtained throughout the ablation cycle from multiple peripheral thermocouples. The RITA system also has perfusion electrodes (see Fig. 52.3) that introduce small amounts of saline into the tissue to enhance the distribution of tissue heating. The third RF system (Cool-tip; Covidien) utilizes a single or triple “cluster” perfusion electrode (three single electrodes spaced 5 mm apart; see Fig. 52.3), the tip of which is positioned in the deepest part of the tumor.

Cold saline or water is pumped internally within the shaft of the electrode to keep its tip cooler than the adjacent heated tissue, thus reducing charring, which in turn helps the thermal conduction to occur at a greater distance from its source. The single or cluster RF electrode contains a thermocouple embedded in its tip, which is used to measure intratumoral temperature. A switching controller can be used with the Covidien system, allowing the placement of up to three separate single electrodes spaced 1.5 to

2.5 cm apart, thus increasing the duty cycle of the generator to enable the creation of a greater volume of tissue thermocoagulation in a single application, as compared with three separate ablations that might be required with a single electrode. Most of the thermal ablation data regarding the treatment of liver tumors has been reported with RFA.¹⁵⁴⁻¹⁵⁶

Figure 52.3 Radiofrequency ablation equipment currently available in the United States. The three most popular generators (left) and needle designs (right) are shown.

Microwave Ablation

Like RFA, microwave ablation (MWA) uses electromagnetic waves to produce heating. Unlike RFA, the MW energy is not an electrical current and is in a much higher frequency range that extends from 300 MHz to 300 GHz. The broader deposition of MW energy creates a much larger zone of active heating. MW applicators available for clinical use generally operate in the 900 to 2,450 MHz range.¹⁵⁷ Microwave tissue heating occurs because of the induction of kinetic energy in surrounding water molecules. Because of their electron configuration, water molecules have highly polar properties and function as small electric dipoles, with the negative charges preferentially localized around the oxygen nucleus. The rapidly alternating electric field of the MW antenna causes water molecules to spin rapidly in an attempt to align with electromagnetic charges of opposite polarity. These spinning water molecules interact with neighboring tissues, transferring a portion of their kinetic energy. Because temperature is merely a proxy measurement of molecular kinetic energy, this energy transfer results in local tissue hyperthermia.

Currently, there are six MWA systems that are commercially available in the United States and Europe.¹⁵⁸ These systems use either a 915-MHz generator (Evident, Covidien; MicrothermX, BSD Medical, Salt Lake City, UT; AVecure, MedWaves, San Diego, CA) or a 2,450-MHz generator (Certus 140, NeuWave Medical, Madison, WI; Amica, Hospital Service, Rome, Italy; Acculis MTA, Microsulis Medical, Hampshire, England) and straight antennae with varying active tips 0.6 to 4.0 cm in length. Perfusion of the antenna shaft is required for five of the six systems, with either room-temperature fluid or carbon dioxide to reduce conductive heating of the nonactive portion of the antenna, thus

preventing damage to the skin and tissues proximal to the active tip. A single applicator is used with a single generator in four of the systems. Two have the ability to power up to three antennae with a single generator and treat large tumors (Fig. 52.4). Because most of the microwave systems have only recently received U.S. Food and Drug Administration approval, there are no published data at this time on the differences between systems in clinical safety or effectiveness. Similar safety and efficacy results for the treatment of metastatic colorectal liver metastases have been reported.¹⁵⁹ Perceived advantages of MW over RF energy include a greater heating profile and less severe heat sink effects.¹⁶⁰ Less heat sink effects may reduce local recurrences, and the larger resultant ablative volume when using the synergistic effect of multiple applicators simultaneously will allow a faster treatment time when compared to RFA.^{161,162} Large trials evaluating safety show a similar safety profile compared with RF.¹⁶³ In Asia, MWA technology has been used for the treatment of liver tumors for a long period of time, and their extensive experience has created the development of appropriate treatment guidelines.¹⁶³

Outcomes of Ablations

To date, the literature is replete with retrospective, single and multicenter cohorts with very few randomized controlled or cooperative group trials evaluating the benefits of liver ablation.

Regardless, many institutions around the world perform liver ablation for primary and metastatic liver tumors given its relative safety, low cost, and low toxicity. Many factors affect the success of thermal ablation treatment for liver malignancies, some of which include: tumor size, proximity to blood vessels, operator experience, the presence of underlying liver disease, extrahepatic disease in patients with secondary liver malignancies, overall patient health, and implementation alongside synergistic therapies in a collegial, multidisciplinary treatment clinic. The ever present argument for surgery as first-line treatment in these patients would be to properly stage the patient because preoperative imaging can underestimate the extent of liver and extrahepatic disease.¹⁶⁴ Of course, not all patients are fit for surgery, and ablation is an attractive minimally invasive option for older and frailer patients. Tumors adjacent to larger (>3 mm) blood vessels may be undertreated due to the thermal sink effect.¹⁶⁵ Proper device selection to effectively eradicate tumors adjacent to vessels should be improved, in theory, with hotter energy sources such as MWA compared to RFA.¹⁶⁶ A novel, largely, nonthermal electrical ablation technology called irreversible electroporation that is purported to be unaffected by thermal sink effects may play a role in treating tumors adjacent to blood vessels and critical structures, but there are no mature data at this time.¹⁶⁷

With a myriad of thermal ablation devices available to hepatic surgeons, hepatologists, and interventional radiologists, studies

Figure 52.4 A 73-year-old man with previously resected colorectal metastatic disease in the left lobe of the liver who recurred in the right lobe despite 5-fluorouracil, oxaliplatin, leukovorin (FOLFOX) chemotherapy. An axial contrast enhanced CT scan and coronal fludeoxyglucose–positron-emission tomography (FDG-PET) CT scan (*top panel*) show a large heterogeneous colorectal cancer (CRC) metastasis in the right lobe. The patient refused additional chemotherapy and ablation was offered as palliative therapy. Given the size of the mass, microwave ablation was performed with multiple antennas under CT guidance (*bottom left*). The patient responded to the treatment extremely well, and a current 20-month follow-up contrast enhanced CT scan (*bottom right*) shows a large coagulation defect (*small arrows*) without evidence of recurrence in the liver.

have shown that it is incumbent upon these operators to gain experience with a particular device before optimal results can be expected.^{164,168} This can be difficult not only in low patient volume ablation practices, but also in general given the rapid technologic changes that occur in this arena whereby a newer technology is perceived to be an improvement over an existing technology prior to rigorous scientific study. The presence of underlying cirrhosis will affect treatment options and outcomes in patients presenting with HCC. In general, HCC patients with Child-Pugh class C cirrhosis who are not on a liver transplant list and do not undergo liver-directed therapies have a median survival of less than 4 months. Therefore, treatment with thermal ablation is unlikely going to affect long-term survival.¹⁶⁹ In patients with Child-Pugh class A cirrhosis, data suggest thermal ablation can rival surgery when tumors are solitary and smaller (<5 cm) and less in number (< three tumors each under 3 cm).¹⁷⁰ However, for patients who are healthier with a normal performance status, surgical resection may provide better long-term survival compared to RFA.¹⁷¹ It makes clinical sense that in patients with limited extrahepatic disease, liver-directed therapy could improve outcomes, although the outcomes themselves may be as much due to underlying tumor biology and not necessarily the treatment.^{154,155} Given the complexity of any given patient with hepatic malignancy, it is important to first and foremost apply any treatment or treatments under the supervision of a team of experts whose primary goal is to provide the most cost-effective, comprehensive treatment based on evidenced-based medicine when available alongside patient centered outcomes.

Liver Resection Versus Ablative Therapy for Hepatocellular Carcinoma

With recent improvements in imaging that allows for the early diagnosis of cancer and facile guidance for interventional therapies, ablative modalities such as RFA are increasingly accepted as effective treatment for small tumors. Ablative techniques are less invasive and have the promise of being better tolerated than resections or transplantation. In retrospective studies, data suggest that for small HCCs (≤ 2 to 3 cm), RFAs result in similar outcomes as resections.¹⁷²⁻¹⁷⁴

Recently, four randomized trials comparing RFA and hepatic resection have been reported (Table 52.8).¹⁷⁵⁻¹⁷⁸ Two of them, Chen et al. and Huang et al., compared tumors fulfilling the Milan tumor criteria for transplantation. Chen et al.¹⁷⁵ compared resection to RFA for tumors less than 5 cm in size. The 1-, 3- and 4-year survivals were 93%, 73% and 64%, respectively, for resection, and 96%, 71%, and 68%, respectively, for RFA. The authors concluded that RFA was as effective as surgical resection in the treatment of solitary HCCs ≤ 5 cm in terms of overall and disease-free survival after 4 years with no significant difference in outcome between the two groups on follow-up. Huang et al.¹⁷⁷ concluded that surgical resections have better outcomes than RFAs. This conclusion was based on a recurrence rate at 5 years of 63% in the RFA group and 41% in the resection group. However, it must be pointed out that more patients in the resected group had tumors less than 3 cm in size. In addition, the overall survival was not statistically different between the two treatment groups.

Feng et al.¹⁷⁸ and Liang et al.¹⁷⁶ confirmed the similar efficacy of RFA to resection in tumors <4 cm. Both groups found RFA and resection to have similar overall survival in a follow-up period after 3 years. It appears that for small HCCs, particularly in patients with cirrhosis, RFA can produce similar cancer outcomes with much lower morbidity. Figure 52.5 illustrates a recommended algorithm of care for small HCCs.

Embolic Therapies for Regional Disease

For patients with multifocal liver-predominant disease who are not candidates for resection or transplantation, transcatheter ablative

methods have emerged as the most commonly used treatment worldwide. These techniques rely on the dual blood supply of the liver: arterial and portal venous. The portal vein provides over 75% of the blood flow to the hepatic parenchyma, whereas the hepatic artery is the primary nutrient supply of tumors. Selectively delivering agents transarterially targets the tumor while sparing the liver.

There are currently three main categories of percutaneously administered transcatheter intra-arterial therapies: TACE, bland hepatic artery embolization (HAE), and radioembolization (RAE). The usual chemotherapeutic agents used are mitomycin C, doxorubicin, and aclarubicin. The majority of the effects of embolic therapies derive from tumor ischemia produced by occlusion of the arterial vessels. Thus, bland embolizations (without chemotherapy), even with a nonpermanent agent such as Gelfoam, can produce a high likelihood of tumor killing. RAE involves the administration of yttrium-90 (a pure β emitter) that can be loaded in glass or resin microspheres intra-arterially.¹⁷⁹ This is really not an embolization, in that the goal is not occlusion of the arterial inflow, but more brachytherapy. RAE will be further discussed.

Patient Selection

Performance status, underlying liver disease, and degree of portal hypertension are important patient selection criteria. Although minimally invasive, following embolization, patients commonly experience a postembolization syndrome of pain, fever, and nausea that may last for several days to a few weeks. It often takes 4 to 6 weeks to recover to baseline performance status.

Although embolization in patients with normal liver, or well-compensated cirrhosis, has a low risk of liver failure, the risk of further compromising liver function and hastening death in poorly compensated cirrhosis is significant. This is because a basis of TACE is that the portal blood flow will protect the noncancerous liver from the treatment agents and ischemia. Thus, portal vein occlusion is considered a contraindication to both TACE¹⁸⁰ and HAE because of the risk of liver failure. Ascites, which is an indication of severe portal hypertension, or measured reversal of portal blood flow is a relative contraindication.

Results of Treatment

It has always been apparent that embolic therapies can result in a high rate of tumor response (>50%). Excellent results (level IIa evidence) following chemoembolization have also been reported from Japan in 8510 patients treated between 1994 and 2001, with 1-, 3-, and 5-year survival of 82%, 47%, and 26%, respectively.²⁹ With well-designed trials, there is also now level I evidence of a survival benefit to conventional TACE as demonstrated in randomized trials published by Llovet et al.,¹⁸¹ Lo et al.,¹⁸² and Becker et al.¹⁸³ In the trial by Lo et al.,¹⁸² patients were randomized to TACE (cisplatin + Lipiodol + Gelfoam) versus control (no treatment). The 2-year survival was 31% for TACE versus 11% for controls. In the trial by Llovet et al.,¹⁸¹ patients randomized to TACE (doxorubicin + Lipiodol + Gelfoam) had a 2-year survival of 63% versus 27% for control. In the study from Becker et al.,¹⁸³ TACE (mitomycin C [MMC] + Lipiodol + Gelfoam) + PEI resulted in a 39% 2-year survival compared to 18% for TACE. What seems clear from these data is that arterial embolotherapy is an effective method of treating HCC and can prolong the patient's survival. Comparable, or better, survival results have been demonstrated with bland embolization.¹¹⁹

Radiation Therapy for Hepatocellular Carcinoma

Radiation therapy for liver tumors was historically limited by hepatic toxicity but, with improved imaging, treatment planning, and treatment delivery, it now is an excellent option, particularly for patients with unresectable tumors or who are medical inoperable.

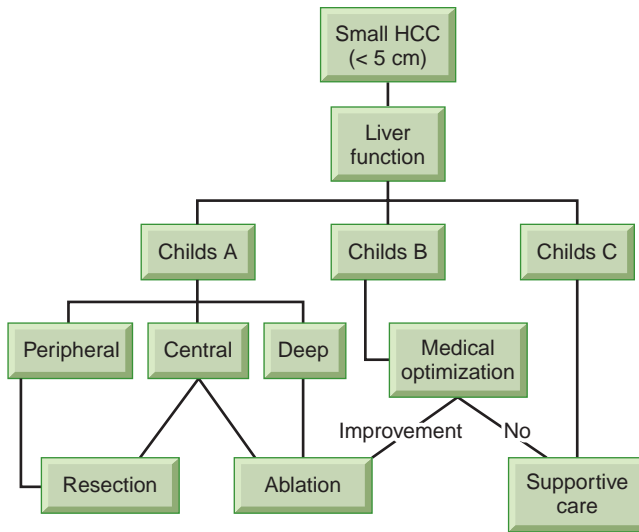

Figure 52.5 The treatment algorithm for a small HCC.

Tumors not likely to be effectively treated by radiofrequency ablation due to size over 3 cm or proximity to the diaphragm, large vessel, or gallbladder are also good candidates for RT. With proper care, tumors near gastrointestinal (GI) structures can also be treated. Side effects are typically minimal, and commonly include mild fatigue, and less commonly include nausea, mild radiation dermatitis, pain associated with tumor edema, or worsening liver dysfunction. Radiation can be delivered using external beam or brachytherapy. Patients with metastases to the bone, brain, adrenals, or other locations can be effectively palliated with RT, as can patients with pain from large primary tumors.¹⁸⁴

External Beam Radiotherapy

Fractionated Treatment

Because the liver is one of the most radiosensitive organs in the body, treatment planning and delivery must be done carefully to maximize dose to the tumor and to minimize dose to the normal liver. The primary toxicity of concern is radiation-induced liver disease (RILD), which can be categorized as classic and nonclassic. Classic RILD is a constellation of anicteric ascites, hepatomegaly, and elevated liver enzymes (particularly alkaline phosphatase), which typically occurs within 4 months of therapy and is a type of veno-occlusive disease, similar to that which can be seen after high-dose chemotherapy conditioning for bone marrow transplantation.¹⁸⁵ Nonclassic RILD, a recently coined classification, can occur in patients with hepatitis and cirrhosis, and is characterized by jaundice and markedly elevated serum transaminases (>5 times the upper limit of normal) within 3 months of completion of therapy. This is thought to represent direct hepatocyte rather than endothelial injury.¹⁸⁶ RILD is typically self-limited, but can be serious, even leading to mortality. It is managed symptomatically, using diuretics and paracentesis. Even low doses to the whole liver of 25 Gy in 10 fractions or 32 Gy in 1.5 Gy per fraction twice daily are associated with a more than 5% risk of radiation-induced liver disease, particularly for patients with cirrhosis and already compromised liver function. Other toxicities that can occur include gastric or duodenal bleeding,¹⁸⁷ although both of these risks can be minimized using careful treatment planning, image guidance, and treatment delivery. It is important to consider factors including cirrhosis, prior liver-directed therapies, and hepatitis B and C, which add to the dose and volume models for the prediction of RILD. ICG is also used in Asia as a pretreatment assessment for the safety

of RT, similar to its use for the safety of liver resection.^{188,189} In the United States, the University of Michigan has pioneered its use to measure individual tolerance to radiation, which can be quite variable. Even some patients with good pretreatment liver function can experience rapid decline, so customizing treatment is crucial.¹⁹⁰

At the University of Michigan, investigators created the normal-tissue complication probability (NTCP) model that quantitatively described the relationship between radiation dose and liver volumes and the probability of developing RILD.¹⁹¹ Dose was customized per patient to give an anticipated risk of 5% to 15%. Due to the variety of tumor and liver sizes and geometries, prescribed doses ranged from 40 to 90 Gy. Patients who received 75 Gy or more had a higher median survival of 24 versus 15 months. Progression-free survival was also improved with higher doses.¹⁹²⁻¹⁹⁵ A prospective phase II trial from France treated patients to 66 Gy in 2 Gy fractions, with a response rate of 92%.¹⁹⁶ The largest published experiences are from Asia, which has a very high incidence of HCC. In a multicenter retrospective patterns-of-care study among 10 institutions in Korea, 398 patients with HCC were described. Of those, 70% were Child class A, 54% had tumors >5 cm, and 40% had portal vein thrombosis. Nearly all had received prior treatment, mostly TACE. In this series, higher dose (biologic effective dose over 53 Gy) also correlated with better survival.¹⁹⁷ Other groups have combined TACE and RT, with various schedules, although mostly using RT to treat residual disease. In a Korean study of 73 patients with incomplete response to TACE, 38 received RT, whereas the rest received additional TACE. Patients who received radiation had a higher 2-year survival of 37% versus 14% ($p = 0.001$).^{198,199}

Another use for RT is to treat tumor thrombus in the portal vein, with the goals of decreasing portal pressure and allowing the safe delivery of embolic therapies. The largest series from Taiwan reports a 25% response rate. Compared with a dismal 1-year survival of 9% for nonresponders, responders had a better survival of 21% for those still not eligible for definitive therapies, and 29% for those who ultimately had additional therapy.²⁰⁰

Other crucial components of a liver RT program not always available for standard RT include adequate imaging with arterial and portal venous phase imaging with CT scans and MRI for tumor delineation, motion assessment, and management tools (four-dimensional computed tomography (4D-CT) scan, treatment gating), and precise image guidance (cone beam CT scan) on the treatment machine. Because liver tumors move with respiration, accurate assessment and management of this will aid in proper tumor targeting and normal tissue avoidance. Some common methods include forced breath hold for tumor immobilization and 4D-CT scans to assess and help account for motion.^{201,202} Fiducials can also be placed within or near the tumor percutaneously prior to treatment planning, with daily alignment on the treatment machine, because external anatomy is a poor surrogate for internal anatomy and tumor location.

Stereotactic Body Radiotherapy

Stereotactic body radiotherapy (SBRT) is a relatively new method of delivering high-dose, high-precision therapy in just a few treatments, rather than spread out daily over a course of several weeks. With high doses per fraction, the biologic effect is much more than with the same total dose delivered in a standard fractionated course, up to the equivalent to 80 to 150 Gy in 2-Gy fractions (see Fig. 52.5). This technique was pioneered by Blomgren et al.,²⁰³ who treated 20 liver tumors, including 8 HCCs in the 1990s. Since then, the literature has mostly been populated by small retrospective studies. A few prospective studies have been quite informative. Mendez-Romero et al.²⁰⁴ initially started treating patients with a schedule of 25 Gy in five fractions, but after two patients experienced local failure, the dose was raised to 30 Gy in three fractions

for the rest of the study. The 1-year local control was 75%, with all failures in the low-dose group. One Child-Pugh class B patient experienced grade 5 nonclassic RILD, leading the authors to advise others to be very cautious with similar patients.²⁰⁴ The next and largest studies were a phase I and II trial from Princess Margaret Hospital.^{205,206} Of 41 initial patients, 31 had HCC. Patients were treated with a six-fraction course of SBRT delivered over 2 weeks, with the dose individualized based on the University of Michigan NTCP model, escalated from 5% to 20%. The median dose was 36 Gy (range, 24 to 54 Gy) and the median tumor volume was 173 mL (range, 9 to 1,913 mL). Even for these relatively large tumors, approximately 50% had a response to treatment, and 42% had stable disease. Median survival was 12 months. No patients developed classic RILD, although 26% had grade 3 elevation of liver enzymes and 16% had a decline from Child class A to B within 3 months after treatment. Recently, the results from the full 102 patients from both the phase I and II portions of the trial were reported.²⁰⁶ Of the patients, 93% had underlying liver disease, 52% had received prior therapy, and 55% had tumor vascular thrombosis. The 1-year local control was excellent, at 87%. However, 30% of patients had grade 3 or higher toxicity, some of which possibly contributed to mortality. This illustrates the tenuous balance between treatment safety and efficacy and the need for improved predictive models of safety for individual patients.

Another phase I study reported 100% local control after 36 to 48 Gy in three to five fractions. Similar to what was seen in the Mendez-Romero study, patients with Child-Pugh class B liver failure were prone to liver toxicity.²⁰⁷ Truly, these patients need extra attention and consideration. Many larger retrospective studies have confirmed these smaller prospective results.²⁰⁸⁻²¹⁰

Charged particles, including protons and carbon ions, are being investigated for treatment of HCC. These have the advantage of lower entrance and minimal exit dose, due to a difference in dose deposition properties. In a Japanese retrospective review, 162 patients were treated with 72 Gy in 16 fractions using protons with a 5-year local control and survival of 87% and 24%, respectively. There were no grade 3 or higher toxicities.²¹¹ In a phase II proton study, 51 patients received 66 Gy in 10 fractions. The 5-year local control and survival rates were 88% and 39%, respectively. There were no cases of RILD, although 26% had a decline in liver function.²¹² Currently, carbon-ion therapy is only available in a few centers worldwide. In Japan, 24 patients were treated on a phase III dose-escalation study. Twenty-four patients received from 50 to 80 Gy in 15 fractions, with local control and survival similar to other reports, at 81% and 25%, respectively.²¹³ Despite the technologic imperative that newer is better, charged particles are not the miracle treatment some may assume. The high-dose treatment region cannot be shaped as conformably as with standard photon radiotherapy (SBRT and intensity modulated radiotherapy [IMRT]), and image guidance is currently rudimentary, therefore, ensuring the accuracy of treatment is difficult. However, because the liver is extremely sensitive to radiation, reducing the moderate and low-dose regions could potentially aid in protecting the normal liver and allowing for escalation of tumor dose. The next few years should yield exciting developments.

Brachytherapy

In contrast to other tumor sites such as prostate, gynecologic, and breast, liver brachytherapy typically involves an injection of a radioisotope for regional therapy, rather than interstitial or intracavitary therapy, although small experiences in interstitial therapy have been reported.^{214,215} Radioembolization, like chemoembolization, takes advantage of the liver's dual blood supply and the arterial enhancement of HCC. Rather than chemotherapy and embolic material, radioisotopes linked to either glass (TheraSphere, Nordion, Canada) or resin (SIRTeX Medical, Inc., Lane Cove, New South Wales, Australia) microspheres are injected into the hepatic artery (HA). This outpatient treatment is typically delivered through

either the right or the left HA, although with favorable anatomy, it can be delivered more selectively. Whole liver treatment is usually reserved for metastases rather than HCC due to the risk of liver injury. The most common isotope is yttrium-90, a pure beta emitter, with an effective path length of 5 mm and a half-life of 65 hours. Ninety percent of the energy is deposited within 5 mm of the sphere, therefore, side effects are quite localized. The dose to the individual tumors is not well characterized, but is prescribed to 80 to 150 Gy, depending on liver function, to the entire treated portion of the liver, assuming equal distribution and based on pretreatment angiography. Side effects are typically quite tolerable and consist of mild nausea, pain, and fatigue. Rare complications could include hepatobiliary dysfunction, radiation pneumonitis, and GI ulceration. Risk factors associated with early mortality include an infiltrative tumor, a tumor encompassing over 50% to 70% of the liver, albumin <3 g/dL, bilirubin >2 mg/dL, and lung dose >30 Gy.²¹⁶ With proper patient selection, this procedure is relatively safe. Although both RAE and chemoembolization can deliver regional therapy, which is particularly useful for multifocal HCC, it is currently unclear which treatment may be preferred for which patients. No randomized trials comparing these two modalities have been completed; however, a retrospective comparison suggests that RAE may have a longer time to progression with reduced toxicity and similar overall survival.¹⁷⁹ In general, response rates are 30% to 50%, with a time to progression of 6 to 16 months depending on stage and portal vein thrombus.^{217,218} Treatment may be repeated.²¹⁹

Toxicities

RT is typically very well tolerated. Mild fatigue can be attributed both to the treatment itself and to the travel related to multiple appointments for the treatment. Mild nausea can be prevented by premedicating with an antiemetic. Radiation dermatitis is highly unusual due to the extremely conformal distribution of radiation dose. Occasionally, the treatment of large tumors can cause a pain flare due to local edema. These acute effects typically resolve within a few weeks after treatment. Late effects could include RILD, as discussed previously, in addition to GI ulceration and renal dysfunction, although these risks can be avoided by minimizing the dose to these structures to below acceptable levels.¹⁸⁷

Systemic Therapy for Hepatocellular Carcinoma

First-Line Single-Agent Therapies

A large number of controlled and uncontrolled clinical studies have been performed with most of the major classes of cancer chemotherapy, given intravenously as single agent or in combination. However, these systemic therapies, and other chemotherapy combinations studied, have had no proven benefits on survival in HCC.²²⁰ Many other nonchemotherapeutic agents have also been tried without definitive success, including luteinizing hormone-releasing hormone agonists, tamoxifen, IFN, Sandostatin, megestrol, vitamin K, thalidomide, interleukin-2, ¹³¹I-lipiodol, and ¹³¹I-ferritin.

Given the vascular nature of HCC and that vascular endothelial growth factor (VEGF) promotes HCC development and metastasis, antiangiogenic agents have been studied extensively in the setting of advanced HCC. Increased levels of VEGF have been observed and have been associated with inferior survival.²²¹

Sorafenib a multi-tyrosine kinase inhibitor with antiangiogenic effects are thought to be mediated by the blockade of VEGFR-2/3, platelet-derived growth factor receptor (PDGFR)- β , and other receptor tyrosine kinases.²²² The clinical efficacy of sorafenib in HCC was first reported in a multicenter phase II study of 137 patients with systemic treatment-naïve, inoperable HCC and varying hepatic reserve (72% Child-Pugh class A, 28% Child-Pugh class B) received the agent, with a primary end point of evaluating response by World Health Organization (WHO) criteria.²²³ Although only

2.2% of the study population achieved a confirmed objective response by WHO criteria, 42% of the study population had extended disease control. There was a median overall survival of 9.2 months, which was encouraging when compared to historical controls. Subsequently, the Sorafenib Hepatocellular Carcinoma Assessment Randomized Protocol (SHARP) trial enrolled 602 patients with advanced HCC, Child-Pugh class A, and who had not received prior systemic therapy.²²⁴ The majority of the study population was recruited from the Western Hemisphere. Patients were randomly assigned to receive sorafenib at 400 mg orally twice a day (N = 299) or best supportive care (N = 303). The coprimary end points of the study were overall survival and time to symptomatic progression. Median overall survival was 10.7 months in the sorafenib arm versus 7.9 months in the placebo arm (hazard ratio [HR] = 0.69; 95% confidence interval [CI], 0.55 to 0.87). A predefined subset analysis indicated that the survival benefit of sorafenib was independent of performance status and disease burden.

Parallel to the SHARP trial, the Asia-Pacific study assessed the efficacy and tolerability of sorafenib in comparison with best supportive care in the patients with advanced HCC geographically localized to Asia.²²⁵ As expected and in contrast to the SHARP trial, the Asia-Pacific study was enriched with patients with HBV-related HCC (73% of the total study population). The trial confirmed that sorafenib, when compared to best supportive care, was tolerable and led to a statistically significant improvement in disease control, time to radiographic progression, and overall survival. However, the magnitude of the overall survival benefit on the Asia-Pacific study was not as substantial as observed on the SHARP study—the median overall survival was only 6.5 and 4.2 months for patients receiving sorafenib and placebo, respectively. The inclusion of patients who were more ill prior to beginning therapy than those patients on the SHARP study might explain this difference. Another postulate is that the observed differential outcomes on the two trials were due to differing treatment patterns between Asia and Western countries. Intense local–regional therapies might be more common in Asia, thus leading to the selection of patients on the Asia-Pacific study who are presenting later in the course of their disease. The inclusion criteria for the Asia-Pacific study, however, do not necessarily support this assertion. Alternatively, specific viral etiologic factors might affect prognosis and influence the responsiveness of liver cancer to sorafenib.

In an unplanned subset analysis of the SHARP study, patients with HBV-related HCC who were treated with sorafenib had a modest prolongation in median overall survival over placebo (9.7 versus 6.1 months).²²⁶ However, HCV-related HCC patients treated with sorafenib appeared to derive a more substantial survival improvement over placebo (14.0 versus 7.4 months). A retrospective analysis of the initial phase II study of sorafenib observed similar etiologic-dependent trends in survival. Patients who were infected with HCV lived longer (N = 13, 12.4 months) than did patients infected with HBV (N = 33, 7.3 months; p = 0.29). The recently reported phase III study of first-line sunitinib indicates that there may in fact be differential outcomes relative to disease cause and ethnic origin, with median overall survival for HCV-associated HCC ranging from 18.3 months for patients with living outside of Asia to 7.9 months for patients living in Asia.²²⁷ Etiologic-dependent genomic differences in HCC might explain improved outcomes to sorafenib in patients with HCV-related HCC. *CTNMB1* mutations are more commonly observed in HCV-related HCC but not in HBV-related HCC and are associated with a specific WNT gene expression profile.²²⁸ Sorafenib can modulate this gene signature, interfere with WNT signaling output, and lead to HCC growth suppression in preclinical models. Etiologic-dependent differences in outcome might also be explained by HCV core protein-induced upregulation of the sorafenib target CRAF, among other kinases.²²⁹ Finally, *in vitro* data suggest that sorafenib can directly inhibit HCV viral replication, although the clinical importance of this observation is debatable.²³⁰ Although more exploration is certainly required, it should be emphasized that the utility of sorafenib

is not undercut by this observation, and it remains an effective and life prolonging therapy for HCC, irrespective of etiologic factor.

Several other small receptor tyrosine kinase inhibitors have been studied. Thus far, emerging results have been disappointing with the major phase III studies of antiangiogenic therapy failing to improve upon sorafenib in the first-line setting. Sunitinib, an inhibitor of vascular endothelial growth factor receptor (VEGFR)-1/2 with greater potency than sorafenib, plus an inhibitor of PDGFR- α/β , c-KIT, FLT3, RET, and other kinases, has been studied in three phase II studies with three different dosing schedules of the agent as a treatment for advanced HCC.^{231–235} A subsequent randomized phase III study of sunitinib, dosed continuously, versus sorafenib in patients with advanced HCC and Child Pugh class A liver function was initiated and rapidly enrolled 530 patients on the sunitinib arm and 544 on the sorafenib arm.²²⁷ The study, powered to test the dual hypotheses of noninferiority and superiority with regard to overall survival, was halted by an independent data monitoring committee due to futility and safety concerns. The median overall survival for the sunitinib arm was 7.9 versus 10.2 months for the sorafenib arm (HR, 1.30; one-sided p = 0.9990; two-sided p = 0.0014).

Brivanib, a dual inhibitor of VEGFR and fibroblast growth factor receptor (FGFR), demonstrated modest antitumor activity in both treatment-naïve and in those patients who had failed prior antiangiogenic therapy in two separate phase II studies.^{234,235} Based on these data, a large randomized phase III study compared brivanib to sorafenib in patients with systemic treatment-naïve, advanced HCC.²³⁶ This noninferiority trial did not meet its primary end point; median overall survival with brivanib treatment was 9.5 months versus 9.9 months with sorafenib (HR, 1.06; 95% CI, 0.93 to 1.22; p = 0.3730).

Linifanib, a selective inhibitor of VEGFR and PDGFR, also failed to improve upon the modest survival advantage of sorafenib despite early encouraging efficacy data.²³⁷ A large multicenter, randomized, phase III study of sorafenib versus linifanib as a first-line therapy for advanced HCC, failed to meet both prespecified end points of superiority and noninferiority. The median overall survival for linifanib was 9.1 months versus 9.8 months for sorafenib (HR = 1.046; 95% CI 0.896 to 1.221).

Over 20 separate clinical trials have assessed or are assessing bevacizumab, a monoclonal antibody directed against VEGF, in patients with advanced HCC. Evaluated regimens include monotherapy and combination therapy with chemotherapy, targeted agents, and embolization procedures. In general, completed studies have reported higher response rates than those observed with other tyrosine kinase inhibitors; however, adverse events such as arterial/venous thrombotic events and variceal hemorrhage (some fatal) are more common. A phase II study in advanced HCC with extrahepatic disease found a 14% overall response rate with bevacizumab monotherapy.²³⁸ It has not moved to later stage trials due to concerns regarding bleeding.

First-Line Combination Therapies

The addition of cytotoxic chemotherapy or targeted therapy to bevacizumab may augment antitumor activity. Response proportions with various cytotoxic combinations range from 9% to 20%, with disease control rates reportedly as high as 78%.^{239–241} Bevacizumab and erlotinib may offer enhanced antitumor activity with a response rate of 24% and favorable patient outcomes with a median overall survival of 13.7 months.²⁴² A multicenter, randomized phase II trial of bevacizumab combined with erlotinib (Clinical Trial: NCT00881751) versus sorafenib monotherapy is ongoing. Similarly, the SEARCH trial confirmed that the addition of erlotinib to sorafenib provided no benefit in HCC. In this randomized, placebo-controlled, double-blind, phase III study the combination of sorafenib and erlotinib were compared to sorafenib alone in the first-line setting in 720 patients with advanced HCC. There was no statistically significant difference

between study arms with regard to the primary end point of overall survival (combination 9.5 months, sorafenib 8.5 months; HR = 0.93; 95% CI 0.78 to 1.11).

In the attempt to improve upon the modest results observed with sorafenib, investigators have proposed combination strategies with cytotoxic chemotherapy and novel biologic agents. Prior to the approval of sorafenib, doxorubicin was evaluated as monotherapy or in combination with sorafenib in a randomized, double-blind, phase II study.²⁴³ The trial enrolled 96 patients with treatment-naïve advanced HCC and Child-Pugh class A liver function. The primary end point of the study was time to progression. In a planned exploratory analysis, both time to progression, as determined by independent review, and progression-free survival were increased by approximately 4 months, and the median overall survival doubled in favor of combined therapy (13.7 versus 6.5 months; $p = 0.006$). Cardiac toxicity was notable, with a higher proportion of patients on the combination experiencing left ventricular systolic dysfunction (19% versus 2%). Although the majority of such cases were asymptomatic, the median cumulative doxorubicin dose was limited to 165 mg/m². The dramatic increase in survival over placebo was striking; however, the lack of sorafenib as a comparator arm limits the interpretation of the trial. Doxorubicin may contribute little to outcome. The observed benefit in the doxorubicin–sorafenib group may be due to the effects of sorafenib alone. Alternatively, the combination may be synergistic. Inhibition of the mitogen-activated protein kinase (MAPK) pathway by sorafenib may restore chemosensitivity by enhancing proapoptotic pathways and dampening multidrug resistance (MDR) pathways. Anthracycline-induced cytotoxicity is mediated by the proapoptotic kinase ASK1.²⁴⁴ Growth factor–induced MAPK activation, via FGF, has been shown to abrogate ASK1 activity. Blockade of the RAF kinases by sorafenib might, therefore, augment the antitumor activity of doxorubicin. Furthermore, MAPK activation leads to the induction of the MDR-1 pump.²⁴⁵ Sorafenib decreases ATP-binding cassette/MDR protein gene expression, thereby restoring HCC sensitivity to doxorubicin *in vitro*.²⁴⁶ A randomized phase III study of sorafenib versus sorafenib and doxorubicin in the first-line setting is currently underway (Clinical Trial: NCT01015833). A phase II study of doxorubicin plus sorafenib in second-line setting after sorafenib failure is currently underway (Clinical Trial: NCT01840592).

Gemcitabine and oxaliplatin (GEMOX) therapy has established efficacy in HCC,²⁴⁷ and there is reason to believe that addition of sorafenib to gemcitabine might offer synergistic antitumor effects.²⁴⁶ The GEMOX–sorafenib versus sorafenib was recently tested in a randomized phase II study (GONEXT).²⁴⁸ The trial enrolled 95 patients with advanced HCC. The primary end point was 4-month progression-free survival of greater than or equal to 50%. The combination of GEMOX plus sorafenib resulted in a 4-month progression-free survival rate of 61% compared to 54% in the sorafenib monotherapy group. The combination was feasible, and efficacy data were encouraging (overall response rate [ORR] 16%, DCR 77%).

Second-Line Therapies

The interest in developing novel agents for advanced HCC and the positive outlook on improved outcome led to a rapidly evolving field studying second-line therapies, with already several phase III clinical trials reported, still on-going, or planned.

Overexpression of c-MET and its ligand hepatocyte growth factor (HGF) occur in up to 80% of human HCC tumors.²⁴⁹ Transgenic mice that overexpress MET in hepatocytes developed HCC, and inactivation of this transgene leads to tumor regression, mediated by apoptosis and growth suppression.²⁵⁰ Blocking MET with several different multitargeted tyrosine kinase inhibitors small molecules induce *in vitro* HCC growth suppression, cell-cycle arrest, and decreased viability as well as growth suppression and survival prolongation *in vivo*.²⁵¹ Based on these data, several MET inhibitors are already being studied in the setting of advanced HCC. Tivantinib, a selective MET receptor tyrosine kinase inhibitor, was

evaluated at two doses in a randomized, placebo-controlled phase II in advanced HCC patients who had progressed after first-line therapy.²⁵² This study reported a statistically significant difference in outcomes between high-MET expressing tumors in favor of tivantinib. For patients with high MET-expressing tumors (defined as $\geq 50\%$ 3 to 4+ expression), tivantinib therapy resulted in a median time to progression of 2.7 months in comparisons to 1.4 months for placebo (HR, 0.43; 95% CI, 0.19 to 0.97) and a median overall survival of 7.2 months versus 3.8 months for placebo (HR, 0.38, 0.18 to 0.81). Importantly, no such differences between the agent and placebo were observed in low-MET expression tumors. This strongly suggests that MET expression is a predictive biomarker for MET-directed targeted therapy in HCC. Additionally, in patients on the placebo arm, high tumoral MET expression was associated with an improved overall survival when compared with low tumoral MET expression (3.8 months versus 9 months; HR, 2.94; 95% CI, 1.16 to 7.43). This observation indicates that MET expression may also be prognostic in this disease. Given these data, tivantinib is being compared with placebo in a double-blind, randomized phase III study in patients with advanced HCC and high-MET expressing tumors in the second-line setting (Clinical Trial: NCT01755767). Cabozantinib, an inhibitor of MET and VEGFR-2, has also shown promising efficacy data in a cohort of 41 patients with advanced HCC.²⁵³ In 78% of patients, tumor regression was observed by Response Evaluation Criteria in Solid Tumors (RECIST) with a 5% confirmed partial response rate. Median progression-free survival for the cohort was estimated at 4.2 months, and median overall survival 15.1 months. A phase III study of cabozantinib versus placebo in patients with advanced HCC in the second-line setting is underway (Clinical Trial: NCT01908426). A different view on the biology of met inhibition differs between those two studies, where the tivantinib approach is to treat only patients with met-positive tumors defined as $\geq 50\%$ 3 to 4+ expression, whereas the cabozantinib study will take all comers, arguing that it is not known yet how much met positivity is needed, if at all, considering the multikinase nature of both drugs.

The mammalian target of rapamycin (mTOR) pathway plays a critical role in hepatocarcinogenesis, and in xenograft mouse models, blockade of this pathway results in HCC growth suppression—but not regression or cellular apoptosis—and in lengthening of survival.²⁵⁴ These observations, as well as retrospective data indicating enhanced survival among patients receiving sirolimus immunosuppression following liver transplantation for HCC, led to the development of a phase I/II study of everolimus established that 10 mg daily was a safe dose.²⁵⁵ The phase II portion, a two-stage efficacy design, did not meet its prespecified boundary for expansion to the second stage. Of 25 evaluable patients, 1 (4%) had a partial response and 10 (40%) had stable disease. Median time to progression was 3.9 months and median overall survival was 8.4 months. Nonetheless, everolimus was investigated in the second-line setting after sorafenib failure in the phase III, randomized, placebo-controlled EVOLVE-1 study (Clinical Trial: NCT01035229) that was recently reported as negative.

A randomized phase III study of brivanib after progression of disease on sorafenib versus best supportive care also failed to meet its primary end point of improved overall survival.²⁵⁶ Among 395 randomized patients, 87% had disease progression while on sorafenib, median overall survival was 9.4 months in the brivanib group versus 8.2 months in the placebo group (HR, 0.89; 95.8% CI, 0.69 to 1.15; $p = 0.3307$). This study's importance lies in defining what may be the true and current median survival of patients with advanced HCC, preserved liver function, and who have failed at least one prior line of therapy. The median survival of such population seems to be better than anticipated and may be reflective of the involvement of multidisciplinary, ensuring better management of patients with advanced HCC. A selection bias, of course, could not be ruled out in the brivanib study as portal invasion and/or thrombosis was noted in 12% of placebo patients versus 25% on the brivanib arm.²⁵⁶

Ramucirumab, a monoclonal antibody blocking VEGFR-2, was recently assessed in a phase II study comprised of 43 patients with systemic treatment-naïve advanced HCC.²⁵⁷ The median progression-free survival was 4 months and the median survival was 12 months. Based on these data, a randomized phase III study of ramucirumab versus best supportive care in the second-line setting is ongoing (Clinical Trial: NCT01140347).

The biosynthesis of the nonessential amino acid arginine occurs as part of the urea cycle and is dependent upon the enzymes argininosuccinate synthetase and argininosuccinate lyase. Messenger RNA encoding argininosuccinate synthetase is not present in subsets of hepatocellular carcinomas; therefore, arginine must be extracted from the circulation.²⁵⁸ Pegylated arginine deiminase (ADI-PEG 20) is an arginine-degrading enzyme isolated from *Mycoplasma* that is formulated with polyethylene glycol (molecular weight: 20 kDa). In preclinical models, ADI-PEG 20 decreases HCC cell viability at low nanomolar concentrations, reduces serum arginine levels to undetectable levels, and prolongs survival in HCC xenograft mouse models. A phase I/II study demonstrated an excellent safety profile in a patient population comprised with a high burden of disease and impaired hepatic function.²⁵⁹ The most common events were injection site reactions and isolated lab abnormalities, such as elevated fibrinogen. Of 19 patients evaluable, 2 (10.5%) had a complete response, 7 (36.8%) had a partial response, and 7 (36.8%) had stable disease. The duration of response ranged from 37 to more than 680 days. A subsequent study reported a disease control rate of 63.1%, a 2.6% objective response rate, and a median overall survival of 11.4 months.²⁶⁰ This exclusively European patient population was composed predominately of HCV-associated (79%) HCC confined to the liver (84%) with otherwise excellent hepatic function (81%). In contrast, Yang and colleagues²⁶¹ tested the agent in a heavily pretreated Asian population with HBV-associated (69%) extrahepatic (58%) hepatocellular carcinoma. In this study, no objective responses were noted and the median overall survival was 7.3 months. Currently, a double-blind placebo-controlled study of ADI-PEG 20 after prior systemic therapy is ongoing (Clinical Trial: NCT01287585).

Systemic Treatments for Patients with Advanced Liver Cirrhosis

Both the SHARP and Asia-Pacific studies were limited to patients with unresectable or metastatic HCC who also had preserved liver function. The benefit of sorafenib in patients with Child-Pugh class B and C has not been established. Sorafenib's safety in patients who are not Child-Pugh class A is of concern. A subgroup analysis of the phase II sorafenib study reported higher rates of hepatic decompensation, represented by worse hyperbilirubinemia, encephalopathy, and ascites in Child-Pugh class B compared to Child-Pugh class A patients.²⁶² Patients in this subgroup had a shorter treatment duration as well as shorter survival in Child-Pugh class B (3.2 months) versus Child-Pugh class A patients (9.5 months). In a Japanese study, there were no differences in the incidence of adverse events between Child-Pugh class A and B groups, despite a geometric means of area under the curve (AUC₀₋₁₂) and maximum serum concentration (C_{max}) at steady state that were slightly lower in patients with Child-Pugh class B cirrhosis compared with Child-Pugh class A.²⁶³ Similar findings have been reported from the phase IV study of sorafenib known as GIDEON.²⁶⁴ Child-Pugh class B and C patients were treated for a shorter duration, had a shorter median survival on sorafenib, and were more likely to develop hepatic and serious drug-related adverse events. A phase I study of sorafenib pharmacokinetics in patients with hepatic dysfunction helped establish some guidance on the use of sorafenib among patients with advanced Child-Pugh score.²⁶⁵ For a serum bilirubin $\leq 1.5 \times$ upper limit of normal (ULN), sorafenib at the full dose of 400 mg twice daily can be given, whereas for a bilirubin 1.6 to $3 \times$ ULN, half that dose should be considered. For albumin < 2.5 mg/dL, no more than 200 mg once daily should be given. There was no safe dose identified for patients

with a bilirubin $> 3 \times$ ULN. Other antiangiogenic therapies have shown to be detrimental in cirrhotics (Fig. 52.6).²³⁷

TREATMENT OF OTHER PRIMARY LIVER TUMORS

Fibrolamellar Hepatocellular Carcinoma

Fibrolamellar HCC is a rare primary liver cancer that differs significantly from the usual HCC. Fibrolamellar HCC occurs in a much younger age group (peak incidence, 3rd decade), is usually not associated with cirrhosis or viral hepatitis, and affects males and females equally. Additionally, a much higher percentage ($> 15\%$) of patients with fibrolamellar HCC presents with positive lymph nodes than normal variant HCC.

Whether the diagnosis of fibrolamellar HCC portends a more favorable outcome after surgical treatment remains controversial.²⁶⁶⁻²⁶⁹ Resection is the first-line of therapy. For those patients in whom the tumor is thought to be unresectable, liver transplantation provides an effective alternative. Pinna et al.²⁶⁹ described 13 patients with fibrolamellar HCC who received transplantation between 1968 and 1995 and reported 1-, 3-, and 5-year patient survival rates of approximately 90%, 75%, and 38%, respectively.²⁶⁹ Given that most patients transplanted presented as young patients with advanced disease, this is not an unacceptable survival rate. El-Gazzaz et al.²⁷⁰ reported similar survival rates. Contrary to what was previously reported, in a large 95 patient retrospective analysis, with 50% presented with stage IV disease, median survival was limited to 6.7 years. Factors significantly associated with poor survival were female sex, advanced stage, lymph node metastases, macrovascular invasion, and unresectable disease.²⁷¹

There is a great need for new, effective systemic therapies for advanced fibrolamellar HCC. A study is underway evaluating everolimus plus estrogen deprivation with leuprolide and letrozole for unresectable fibrolamellar HCC (Clinical Trial: NCT01642186).

Hepatoblastoma

Hepatoblastoma is the most common primary cancer of the liver occurring in childhood. The annual incidence of hepatoblastoma ranges from 0.5 to 1.5 cases per million children, with a peak incidence occurring within the first 2 years of life.²⁷² Hepatoblastoma is highly sensitive to chemotherapy, which often renders unresectable tumors resectable. Surgical resection is considered the first line of therapy. However, for those tumors that cannot be converted to resectable lesions but without distant metastasis, most can be rescued with liver transplantation. Survival rates for these children after liver transplantation is excellent, with 1-, 3-, and 5-year survivals reported at 92%, 92%, and 83%, respectively.²⁷²

Epithelioid Hemangioendothelioma

Epithelioid hemangioendothelioma is a very rare tumor of vascular origin that can originate in the liver; it occurs predominantly in females. The tumor is often confused with other more aggressive cancers, particularly cholangiocarcinoma, angiosarcoma, and HCC. The clinical course of epithelioid hemangioendothelioma is quite variable. In the review by Makhlof et al.,²⁷³ 137 cases were described, and survival ranged from 4 months to 28 years. Of interest, one patient who received no treatment survived for 27 years without evidence of metastasis. Surgical resection is considered to be the treatment of choice. However, in multifocal disease, a short observation may be reasonable to help decide between observation, ablation, resection, or transplant as the course of action. The presence of metastatic disease does not seem to influence survival and should not be considered an absolute contraindication to either surgical resection or transplantation.

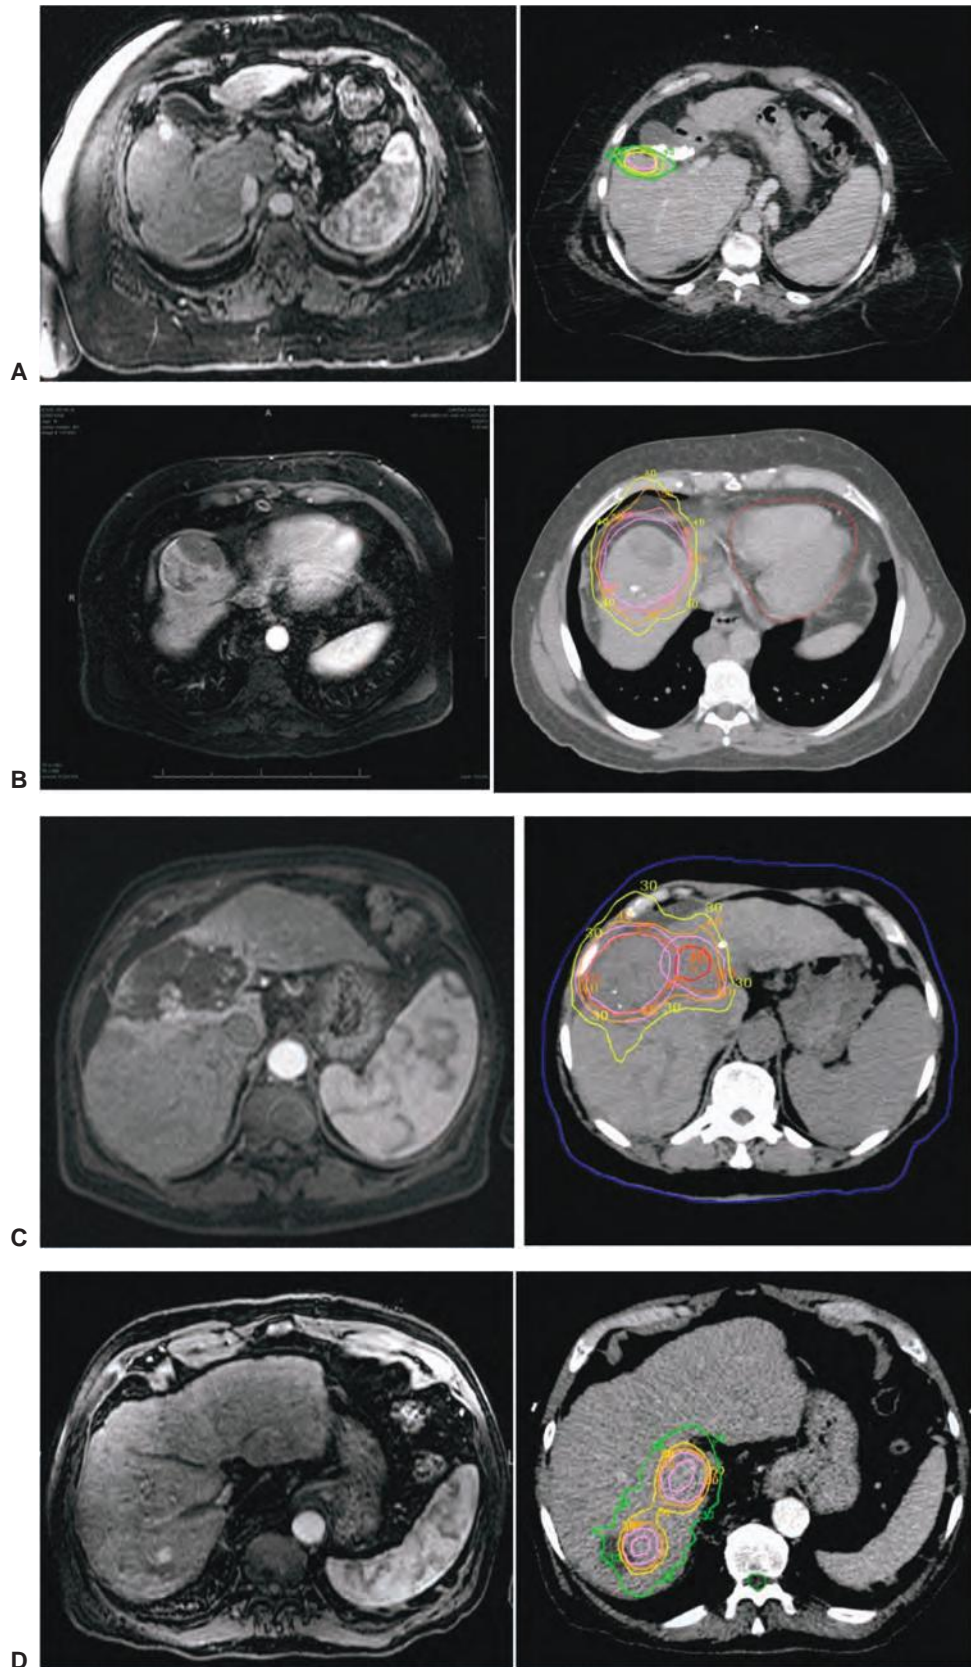

Figure 52.6 An SBRT can be used to treat single (A, B) or multiple (C, D) tumors in three to five high-dose, highly focused treatments. Planning is typically performed by fusing MRI images (A, C) with a planning CT scan (B, D) for accurate targeting. Special attention must be given to minimizing radiation dose to the remaining liver, particularly for patients with preexisting liver dysfunction.

53 Cancer of the Biliary Tree

Tushar Patel and Mitesh J. Borad

INTRODUCTION

The biliary tract or the biliary drainage system includes the intra- and extrahepatic bile ducts and the gallbladder. Cancers associated with the biliary tract may be associated with biliary tract epithelia along the entire biliary tract from the intrahepatic ductules to the ampulla of Vater.

Cholangiocarcinomas are cancers of the biliary tract that are associated with the intrahepatic or extrahepatic bile ducts. The term *cholangiocarcinoma* encompasses three distinct tumor types that vary in their risk factors, presentation, natural history, and management.^{1,2} Intrahepatic cholangiocarcinomas (iCCA) arise from the intrahepatic biliary tract beyond the second order ducts. Distal extrahepatic cholangiocarcinomas (dCCA) arise from the common hepatic duct extending up to the junction with the cystic duct up to the papilla. Perihilar cholangiocarcinomas (pCCA) arise from the second order ductal division within the liver and the large extracellular ducts up to the confluence with the cystic duct. In addition to cholangiocarcinomas, cancers such as gallbladder cancer and some ampullary cancers also arise from the biliary tract.

The presentation, diagnosis, and management of intrahepatic, perihilar, and distal cholangiocarcinomas and of gallbladder cancer are separately described in this chapter.

Periampullary tumors can arise from biliary as well as pancreatic, duodenal, or ampullary tissues. The presentation, evaluation, and management of periampullary tumors of biliary tract origin are identical to those of any of the other types of periampullary tumors, namely pancreatic, duodenal, or ampullary tumors. In most instances, the distinction between the tissue type of origin is obscure or may only be made on a histopathologic examination. These cancers will not be described in this chapter.

As a group, cancers of the biliary tract are rare. They are often diagnosed at an advanced stage and are associated with a poor prognosis. Management of these patients requires a multidisciplinary approach by a team with experience in their management and which includes hepatobiliary surgeons, hepatologists, gastroenterologists, diagnostic and interventional radiologists, pathologists, medical oncologists, and radiation oncologists. If the relevant and necessary expertise is not available locally, an early referral to experienced centers should be considered.

ANATOMY OF THE BILIARY TRACT

The biliary tract consists of the intrahepatic and extrahepatic bile ducts and is responsible for transporting bile from the liver to the intestine. Development of bile ducts requires complex intercellular interactions and signaling. Notch signaling is a critical determinant of both biliary differentiation and morphogenesis leading to the formation of normal bile ducts. Activation of Notch in liver progenitor cells results in differentiation to biliary ductal cells, whereas activation of Notch signaling in the hepatic lobule promotes ectopic biliary differentiation and duct formation. Experimentally enforced Notch signaling in adult murine hepatocytes causes them to reprogram to a biliary phenotype and can result in cholangiocarcinoma formation.

Within the liver, bile ducts along with branches of the hepatic artery and portal vein constitute the portal triad, which is directed to each lobule of the liver. The adult liver is divided into eight segments delineated by blood supply and venous drainage. These segments delineate and guide the resections of the liver. The main left hepatic duct exits the liver at the base of the umbilical fissure, and the main right hepatic duct exits the liver between segments V and VI. The caudate lobe drains directly into the left main hepatic duct via numerous small branches.

The confluence of the right and left hepatic ducts occurs in the hilum. The porta hepatis consists of the bile duct, the portal vein, and the hepatic artery, from right to left. At the hilum, the portal vein is posterior; the right hepatic artery generally passes between the common bile duct and the portal vein; and the cystic artery passes anterior to the bile duct. The proximity of the portal vein and hepatic artery to the bile duct in the hilum leads to early vessel involvement or occlusion from pCCA, which affects the options for surgical resection. Arterial anomalies are common, and if not recognized, could lead to inadvertent injury during dissection within the porta hepatis.

The cystic duct may enter the common duct near the confluence of the right and left ducts, or distally near the duodenum. It may also enter the right hepatic duct. The distal bile duct travels posterior within the head of the pancreas and then joins the pancreatic duct in a common channel leading to the ampulla of Vater.

The lymph node drainage of the bile ducts involves the superior pancreaticoduodenal, retroportal, or proper hepatic nodes first, then the peripancreatic, celiac, and interaortocaval lymph nodes.³ Lymph nodes in the porta hepatis may be difficult to remove because of attached venous branches from the portal vein or fixation of tumor-involved lymph nodes to the bile duct, portal vein, hepatic artery, or the head of the pancreas. However, a multi-institutional cohort study reported that the presence of lymph node metastases significantly and adversely affected patient survival (hazard ratio [HR], 2.21; $p < 0.001$), and may explain the survival benefit of a lymphadenectomy for iCCA.

The location of the primary tumor within the gallbladder and the proximity of the portal vein, hepatic artery, and bile duct are all important factors in the surgical management of this tumor. The gallbladder is attached to segments IVb and V of the liver, and these segments may be involved early in tumors of the fundus and body of the gallbladder. The gallbladder has a thin mucosal wall, a narrow lamina propria, and only a single muscle layer. Once this is penetrated, the tumor can access major lymphatic and vascular channels leading to early lymphatic and hematogenous spread. Tumors of the infundibulum or cystic duct can also obstruct the common bile duct and may involve the portal vein.

The lymphatic drainage of the gallbladder first involves cystic and pericholedochal nodes, before extending to nodes posterior to the pancreas, portal vein, and common hepatic artery. Finally, the flow reaches the interaortocaval, celiac, and superior mesenteric artery lymph nodes. Node-bearing adipose tissue posterior to the head of the pancreas and portal vein may be involved early, whereas drainage to the hilum does not occur.⁴ Direct connections may exist from the pericholedochal nodes to

the interaortocaval nodes, limiting the ability to control disease spread with a regional lymph node dissection.

The upper abdomen contains many organs with relative low tolerance to radiation, such as the spinal cord, kidneys, liver, stomach, duodenum, and small bowel. The tolerance of these at-risk organs poses significant limitations to the dose used in radiation therapy.

CHOLANGIOCARCINOMA

Nomenclature of Cholangiocarcinoma

The nomenclature used for cholangiocarcinomas has evolved over time and has been variably applied. As an example, epidemiological reports have either included perihilar tumors with iCCA or as extrahepatic tumors with dCCA. In addition, iCCA have long been reported along with other primary tumors of the liver. Because of the failure to recognize the different tumor types, the true incidence, prevalence, and natural history are not well established. The relative distribution of tumors within the biliary tract is also unclear. pCCA are the most common type of cholangiocarcinoma (CCA) worldwide. In one study, only 8% of cholangiocarcinomas seen were iCCA.⁵ However, these data are not supported by clinical observations in practice and do not accurately reflect disease distribution because they are from a single center series and influenced by referral patterns.⁵ The seventh edition of 2010 American Joint Committee on Cancer (AJCC) staging system classifies each of type of cancer of the biliary tract as separate entities with distinct staging and biologic properties.⁶

Classification of all of these diverse cancers as a single group of biliary tract cancers has resulted in a lack of recognition of their distinctive clinical behavior, nature, and management. The individual risk factors and specific molecular pathogenesis of iCCA, pCCA, or dCCA are also not well understood. Likewise, a lack of distinction between these cancers in therapeutic clinical trials has limited progress in identifying useful and optimal therapies for the individual types of cancers. Most clinical studies have included all types of biliary tract cancers, including gallbladder cancer and ampullary cancer, and have reported results in an aggregate fashion. Although specific etiologic and molecular differences are now becoming recognized, an improved understanding will emerge only once these distinctive cancer types are recognized as separate cancers in future population-based reports, patient-based studies, or laboratory investigations.

Etiology of Cholangiocarcinoma

Risk Factors

Although these cancers often occur sporadically without any identifiable risk factors, there are some well-defined risk factors. These include infections, conditions resulting in chronic biliary tract inflammation, drug/toxins, or congenital causes.^{1,7-11} Because the individual risk factors for the different types of cholangiocarcinoma have not yet been delineated, we will review common risk factors associated with these cancers in this section. Where tumor specific risk factors are known, they will be discussed in the relevant sections.

Infestation with *Opisthorchis viverrini* and *Clonorchis sinensis* results in chronic inflammation of the bile duct, and are associated with CCAs. These two parasitic liver flukes are classified as group I carcinogens by the International Agency for Research on Cancer.¹² These liver flukes are highly prevalent in certain geographic regions such as Southeast Asia and, in particular, in Northeast Thailand. The geographic restriction of liver flukes has resulted in a highly variable disease prevalence in different parts of the world varying from 87 per 100,000 in Thailand to 1 to 2

per 100,000 in the United States.¹³ Liver fluke infection with *O. viverrini* or *C. sinensis* species is associated with ingestion of raw fish containing the larva of liver flukes. Infestation is reversible with treatment with praziquantel. The degree of infestation as measured by stool egg count is related to the risk for CCA. Liver fluke infestation is associated with intrahepatic stones as well as with elevated nitrates, and animal and human studies suggest that N-nitroso compounds may be involved in carcinogenesis. The diagnosis of cancer is often difficult and delayed. Once cancer develops, the prognosis is similar to that of CCA in patients that do not have a fluke infestation.

Other infectious diseases that have been associated with CCA include HIV, and chronic hepatitis B virus (HBV) and hepatitis C virus (HCV) infections.¹⁴ A recent meta-analysis of case-control studies reported an increased risk of iCCA in patients with HBV and HCV infection.^{15,16} There appear to be regional differences in the risk of chronic hepatitis associated iCCA, although these are not well characterized.

Inflammatory conditions are less common, but their prevalence is more widely distributed. Primary sclerosing cholangitis (PSC) is an autoimmune condition affecting the biliary tract and characterized by inflammation within the biliary tract and subsequent development of diffuse multifocal biliary ductal strictures. CCA can occur in 5% to 10% of patients with PSC¹⁷ and occurs more frequently in patients with chronic ulcerative colitis than in the general population.¹⁸ A high incidence of CCA occurs in patients with coexisting PSC and ulcerative colitis.¹⁹ Up to 50% of patients with PSC with CCA have this diagnosed within a year of their initial diagnosis with PSC.²⁰ The presence of underlying liver dysfunction resulting from biliary tract disease complicates surgery or chemotherapy.²¹

Chronic calculi of the intrahepatic and extrahepatic bile ducts (hepatolithiasis) outside the gallbladder is rare, but predisposes one to cancer formation. In Southeast Asia, chronic portal bacteremia and portal phlebitis are associated with intrahepatic pigmented stones, and subsequently, increased risk of cholangiocarcinoma. Cancers may develop even after stone removal, potentially related to stasis and cholangitis related to fibrosis induced by stone disease.²²

An anomalous pancreatic–biliary duct junction may lead to a chronic inflammatory state in the bile duct via reflux of pancreatic juice into the biliary tree. This has been associated with an increased risk of CCA.²³

Biliary tract cystic diseases are associated with an increased risk of malignancy, which can arise in noncystic portions of the biliary tract. Tumors can occur in patients with untreated choledochal cyst disease.^{24,25} A choledochal cyst is a rare condition, manifest by congenital cystic dilatation(s) of the bile ducts. Bile stasis in the cysts leads to chronic inflammation of the duct. Of patients with choledochal cysts, 10% to 20% will develop CCA if left untreated or managed with surgical drainage alone.²⁶ Early excision of the choledochal cyst has been proposed to reduce the risk of CCA. Caroli disease is a rare variant of choledochal cysts that results in intrahepatic ductal dilatation and an increased risk of developing CCA.²⁷

Recent epidemiologic studies indicate that occupational exposure to asbestos or to certain volatile compounds used in the printing industry such as 1,2-dichloropropane may also increase the risk of cancer.^{28,29} Exposure to dioxin has also been implicated, although the data are not conclusive. Other potential carcinogens include radionuclides, radon, and nitrosamines.³⁰ Thorotrast (thorium dioxide) is a vascular contrast agent that is associated with an increased risk of cancer, but has not been used since the 1940s.³¹ The risks associated with cigarette smoking are not well quantified.^{15,30}

Recently, liver cirrhosis has been identified as a risk factor for iCCA.¹⁵ Consistent with this observation, risk factors for cirrhosis, such as chronic hepatitis C, chronic hepatitis B, and alcohol, are also associated with a higher risk for iCCA.^{15,32,33} Because these are

also dominant risk factors for hepatocellular cancers, these observations suggest potential common risk mechanisms of tumorigenesis in liver epithelia.

Molecular Pathogenesis of Cholangiocarcinomas

The mechanism and events responsible for neoplastic transformation in the biliary tract are not well understood. It is postulated that chronic inflammation and infection in biliary epithelia and their interactions with other stromal cells' active inflammatory signaling such as those involving interleukin-6 (IL-6), inducible nitric oxide synthase (iNOS), and cyclooxygenase 2 (COX-2).³⁴ These result in a proliferative stimulus to epithelial cells involving epidermal growth factor receptor (EGFR), RAS/mitogen-activated protein kinase (MAPK), IL-6, or MET signaling. Malignant transformation occurs in the setting of genetic alterations and epigenetic changes on this background, and results in the deregulation of several signaling pathways that can enhance malignant cell growth, apoptosis, and tumor cell behavior. Tumors may arise from malignant transformation of biliary epithelial cells, progenitor cell populations, or transdifferentiation of hepatocytes.

Several genetic and epigenetic alterations and deregulated signaling pathways have been identified.³⁵ In PSC, inflammation results in the activation of the nuclear factor κ B (NF- κ B) signaling and increased tumor necrosis factor alpha (TNF- α) and IL-6. IL-6 is an important contributor to cholangiocarcinogenesis and has been associated with several molecular events such as alterations in EGFR, p38, and p42/44 MAPK and altered let-7 microRNAs.³⁴ Alterations in hepatocyte growth factor/MET signaling and in the EGFR family with overexpression of EGFR and HER-2/*neu* have been identified. Autocrine growth loops have been identified, involving hepatocellular growth factor (HGF)/MET and IL-6/glycoprotein 130 (*gp130*).³⁶ Alterations in the glycosylation of mucins (MUC proteins) and sialosyl-Tn antigen may be relevant, although their contribution is not well defined.³⁷

Genetic alterations that have been identified, including activating mutations of KRAS, loss of TP53, mutations in IDH2 and IDH1, and rarely, alterations in BRAF, NRAS, and PI3K.^{35,38–40} Tissue-specific activation of the *K-ras* G12D mutation in genetically engineered mice results in invasive iCCA, which is augmented by the addition of a loss in p53.⁴¹ Mutations of *Her-2/neu* and *c-MET* have also been reported.⁴² The genetic mutations observed may vary with type of tumor. Thus, IDH1/2 mutations are not seen with pCCA or dCCA, but may occur in up to 25% of iCCA, whereas *K-ras* mutations are more common in the former.^{43,44}

Notch signaling is a complex, evolutionarily conserved pathway that is needed for normal bile duct development. Notch and several of its downstream targets SOX9, sex determining region Y-box 9, and hepatocyte nuclear factor 1 β , may be involved in CCA pathogenesis. SOX9 is strongly expressed in intrahepatic bile ducts. Loss of SOX9 in CCA is associated with higher tumor grade and stage, and is an independent adverse prognostic factor for survival.⁴⁵ Nuclear colocalization of delta-like ligand 4 (*DLL4*) with Notch receptor 1 or 3 was associated with nodal metastases, less histologic differentiation, and worse survival of extrahepatic CCA and gallbladder cancer.

In addition to genetic changes, epigenetic changes resulting from alterations in promoter methylation of tumor suppressor genes such as SOCS-3, RASSF1A, p14ARF, and p16^{INK4A} as well as changes in some microRNAs such as miR-21 and miR-200c have been described.³⁵ Genomic studies have started to identify distinct subgroups of iCCA on patterns of gene expression, but these need to be validated and their clinical applications defined.^{35,46–48}

Although the specific molecular pathogenesis of pCCA tumors is unknown, it is postulated that tumorigenesis results from a similar sequence of events to that described previously with the additional contribution of cholestasis. The reasons for the predilection

of these tumors to occur in the hilar region are not clear. Morphologically and genetically, pCCA more closely resemble extrahepatic dCCA than iCCA. The pathogenesis of pCCA and dCCA is presumed to be similar to that described for iCCA, with an additional contribution of cholestasis. Some of these tumors may originate from progenitor cell populations in the submucosal glands, and in tumors that have maintained differentiation, mucin production may be prominent. A subtype of iCCA may arise from a progenitor cell within the liver that results in tumors with histologic and genetic features of mixed hepatocellular carcinoma-cholangiocellular carcinoma.

A sequence of progression from normal mucosa to adenomatous hyperplasia, dysplasia, carcinoma in situ, and then invasive cancer similar to that described for other mucosal cancers may also occur in the biliary tract. Two precursor lesions are identified: biliary intraepithelial carcinoma neoplasia, which is more common, and intraductal papillary neoplasm of the bile duct.³⁸

Pathology of Cholangiocarcinomas

Gross Morphology

The gross morphology can be exophytic, (nodular) mass forming, intraductal, or periductal infiltrating (or sclerosing). Mass-forming and periductal infiltrating (or both combined) are the most common types encountered. iCCAs are more likely to be nodular and mass forming, whereas pCCAs and dCCAs are more likely to be sclerosing, although not exclusively so. The sclerosing type is associated with an intense desmoplastic reaction and often manifest as diffuse thickening of the ducts without a defined mass. The nodular type tends to result in a mass lesion and usually arises within the liver. Intraductal tumors are less common and can encompass a range of lesions from preneoplastic to invasive carcinomas. In some patients, dCCAs may present only as a thickened bile duct wall involved in a dense fibrous scar. Polypoid or papillary cancers have the best prognosis. Papillary cancers represent a low-grade adenocarcinoma that is represented by a polypoid mass filling the lumen of the bile duct, with minimal invasion and no desmoplastic reaction.⁴⁹

Histology

More than 90% of tumors are epithelial adenocarcinomas.⁵⁰ Other variants include well-differentiated, pleomorphic, giant cell, adenosquamous, oat cell, and colloid carcinomas. Other types, such as squamous cell carcinomas, sarcomas, small cell cancer, and lymphomas account for less than 5%. Sclerosing tumors are characterized by an extensive fibrous stroma with interspersed tumor cells. Papillary tumors may have papillary fronds with extension into the bile duct lumen, and may produce extracellular mucin. Nodular mass-forming tumors may vary with appearances akin to sclerosing type or with tubular pattern. Satellites are common and may result from spread along the bile ducts or from vascular invasion and intrahepatic metastatic spread. Regional lymph node metastases and perineural invasion are common with pCCAs and dCCAs. Distant metastases can occur, but are unusual.⁵¹

Intrahepatic Cholangiocarcinoma

Incidence and Etiology

iCCAs are cancers of the biliary tract that arise from intrahepatic bile ducts beyond the second order ductal system within the liver. They are the second most common primary epithelial malignancy of the liver, but are uncommon cancers in the United States. The incidence and mortality from iCCAs have been reported to be increasing in the United States and in many other countries.^{52,53} The incidence of these cancers increases with age, with the majority of patients aged 65 years or older. Patients with

defined risk factors such as PSC or choledochal cysts tend to develop tumors at a younger age. These tumors are slightly more common in men. There are racial and ethnic variations prevalent, with the highest prevalence among Hispanics in the United States (1.22 per 100,000) and the lowest among African Americans (0.3 per 100,000).⁵⁴

Diagnosis

Patients with iCCAs may be asymptomatic, with the initial presentation being a mass lesion within the liver. When symptoms occur, these may include nonspecific right upper quadrant pain, or weight loss. In contrast to pCCAs or dCCAs where obstructive jaundice occurs early, jaundice occurs late with iCCAs and usually indicates extensive disease.⁵⁵ Occasionally, a centrally located iCCA may present with jaundice due to extrinsic compression of the main ducts. Other presentations are rare, and include mucobilia or a tumor embolizing into the extrahepatic bile ducts, resulting in pain, jaundice, or even pancreatitis.⁵⁶

The diagnosis of iCCA involves demonstrating a mass lesion within the liver using abdominal computed tomography (CT) or magnetic resonance imaging (MRI).⁵⁷ On CT scan, the lesion is usually of low attenuation with only mild enhancement seen with contrast.⁵⁸ On a T1-weighted MRI, iCCAs are usually of low intensity, but may have high intensity on T2-weighted images. Centripetal filling in after gadolinium administration may be observed on MRI. Ductal dilation is often present peripheral to the tumor. Local vascular invasion is often seen by CT scan, MRI, or angiography.^{59,60}

The differential diagnosis includes hepatocellular cancer (HCC) or metastatic cancer from other primary tumors. Cirrhosis is a risk factor for both iCCAs and HCCs. Imaging findings are often used to diagnose liver masses as HCCs without obtaining a biopsy. Characteristic imaging features of iCCAs that may be helpful in distinguishing these tumors from HCCs are slow uptake of contrast, particularly in highly desmoplastic tumors, and a peripheral rim of enhancement. A liver biopsy should be considered for a diagnosis if the tumor is inoperable due to extensive spread or if other lesions such as focal nodular hyperplasia are strongly suspected. Otherwise, in potentially resectable cases, further staging studies, including a laparoscopy, would be considered.

Grossly, iCCAs may be well or poorly demarcated, single, or multiple. Mucin production, fibrosis between the acini of tumor tissue, and a more overtly glandular pattern are the main differentiating characteristics from HCC.

Immunohistochemical staining for specific cytokeratins may also be helpful. Unlike HCCs, some cholangiocarcinomas stain positively for CA19-9 or carcinoembryonic antigen (CEA), or $\alpha\text{v}\beta 6$ integrin, but not for hepatocyte antigen.⁶¹ It may be difficult to distinguish iCCA from a liver metastasis of extrahepatic origin if a cytological analysis shows adenocarcinoma. Cytokeratin 7 or cytokeratin 20 may be helpful to establish a biliary origin. Cytokeratin 20 expression is focal and rare in iCCAs in contrast to being diffuse and common in colorectal cancer metastases.⁶² If a primary site cannot be identified, a diagnosis of iCCA should be presumed.

Staging

The tumor-node-metastasis (TNM) system devised by the AJCC should be used for staging these cancers.⁶ The seventh edition (2010) separated the staging of iCCAs from that of hepatocellular cancer, as well as from perihilar or distal CCAs. Table 53.1 shows the staging system for iCCAs.

Management

Most treatment information has been derived from small series gathered over several years, with variable definitions of disease used and, therefore, the best approaches to treatment are not clarified. Consensus guidelines have been proposed for management.^{63,64}

TABLE 53.1

American Joint Committee on Cancer TNM Staging for Intrahepatic Cholangiocarcinoma

Primary Tumor (T)			
TX	Primary tumor cannot be assessed		
T0	No evidence of primary tumor		
Tis	Carcinoma in situ (intraductal tumor)		
T1	Solitary tumor without vascular invasion		
T2a	Solitary tumor with vascular invasion		
T2b	Multiple tumors, with or without vascular invasion		
T3	Tumor perforating the visceral peritoneum or involving the local extrahepatic structures by direct invasion		
T4	Tumor with periductal invasion; the pathologic definition of periductal invasion is the finding of a longitudinal growth pattern along the intrahepatic bile ducts on both gross and microscopic examination		
Regional Lymph Nodes (N)			
NX	Regional lymph nodes cannot be assessed		
N0	No regional lymph node metastasis		
N1	Regional lymph node metastasis present		
Distant Metastasis (M)			
M0	No distant metastasis		
M1	Distant metastasis present		
Anatomic Stage/Prognostic Groups			
Stage 0	Tis	N0	M0
Stage I	T1	N0	M0
Stage II	T2	N0	M0
Stage III	T3	N0	M0
Stage IVA	T4	N0	M0

An algorithm for the management of these cancers is shown in Figure 53.1.

Surgery. Indications for resectability are not well described. The goal is to resect the tumor with an adequate margin of normal tissue, and to obtain microscopically free resection margins, while retaining enough liver tissue behind for the patient to have adequate liver function after surgery. The resection may vary from nonanatomic resections to segmental anatomic resections. Intrahepatic metastases tend to occur as multiple satellites, and although their presence impacts prognosis, it should not define resectability. However, for widespread hepatic metastases, curative resection is unlikely, and other forms of therapy should be considered. The presence of underlying advanced cirrhosis with portal hypertension may preclude surgical resection. Extrahepatic spread portends a poor prognosis, and carcinomatosis should be considered a contraindication to resection. A staging laparoscopy can help define resectability prior to a full laparotomy and is recommended.⁶⁵

Outcomes after surgical resection for iCCAs have been reported in small series in the literature. The resectability rate ranges from 32% to 90%. The mortality of resection is slightly higher than se-

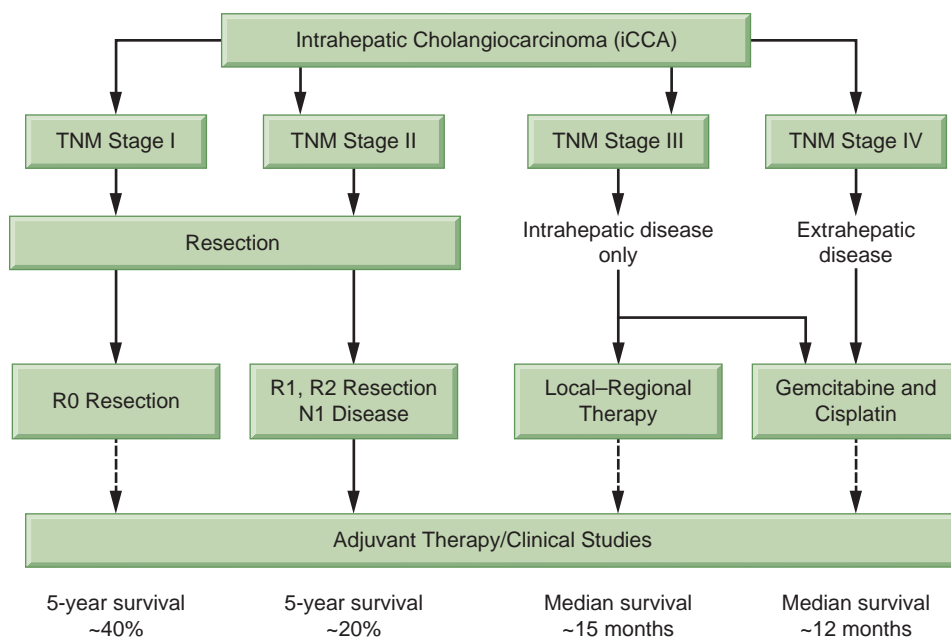

Figure 53.1 Algorithm for the management of intrahepatic cholangiocarcinoma.

ries of hepatic resection for other indications, but is generally less than 10%. Lymph node metastases, positive margin status, and vascular invasion were reported as significant prognostic factors in an analysis of 449 patients.⁶⁶ Other prognostic factors include satellite metastases, nodal metastases, tumor size, and a CA19-9 level greater than 1,000. Although rare, intrahepatic intraductal papillary tumors have an excellent prognosis if completely resected.^{67,68}

The median survival after surgical resection is ~36 months. The 5-year survival rate with a curative R0 resection is ~60%, but curative resections are possible only in about 30% of patients. There is high risk of tumor recurrence both locally with intrahepatic metastases as well as with extrahepatic disease. However, there are no established guidelines for surveillance and follow-up after surgical resection for iCCAs. As a guide, surveillance could consist of laboratory tests of liver function and CA19-9 and radiologic evaluations every 3 months for the first 2 years after surgery and every 6 months thereafter for the first 5 years could be considered and modified based on the perceived risk. The role and utility of surveillance has not been formally established. Surgery is generally not indicated for recurrent CCAs.

Liver Transplantation. The outcomes from liver transplantation for iCCAs, unlike those for hilar CCAs have been disappointing, with a 5-year survival rate of 29% in data from the European Liver Transplant Registry.⁶⁹ As a result of these poor outcomes, liver transplantation is not generally offered for this indication.

Local-Regional Therapies. Local-regional therapy for unresectable iCCAs include transarterial chemoembolization (TACE), transarterial radioembolization (TARE), radiofrequency ablation (RFA), or microwave ablation. They may be used for palliation and local control in persons with a good performance status. A median survival time of 20 months with TACE and 43.7 months with TARE have been reported in case series. For tumors smaller than 3 cm, RFA resulted in a median survival time of 38.5 months. Most tumors present with a large bulky tumor precluding complete ablation, and there is a potential risk of biliary complications arising from bile duct damage.

Chemotherapy. Based on pivotal data from the UK-ABC-02 study, gemcitabine in combination with cisplatin has been

established as the standard of care for patients with biliary cancers.⁷⁰ Gemcitabine was dosed at 1000 mg/m² in combination with cisplatin at 25 mg/m², with both agents given intravenously on days 1 and 8 every 21 days for a maximum of 6 months. The study was conducted using a phase II/III design and enrolled 410 patients across centers in the United Kingdom. Stratification was done based on the extent of disease (locally advanced versus metastatic), primary tumor site (intrahepatic/extrahepatic bile ducts, ampullary, gallbladder), performance status (Eastern Cooperative Oncology Group [ECOG] score 0, 1, or 2), prior therapy (yes/no), and recruiting center. The median overall survival in the gemcitabine/cisplatin group was 11.7 months compared to 8.1 months in the gemcitabine only group ($p < 0.001$; 95% CI, 9.5 to 14.3) with a hazard ratio of 0.64 (95% CI, 0.52 to 0.80). Efficacy was evident across a range of endpoints, including progression-free survival (8 months versus 5 months; HR, 0.63; $p < 0.001$) and response rate (26.1% versus 15.5%). Prespecified subgroups described earlier all derived clinical benefit. Only 17.6% (72 of 410) patients went on to receive second-line therapy. The role of subsequent lines of therapy with regard to survival benefit remains to be defined, but fluoropyrimidine-based regimens have demonstrated preliminary evidence of efficacy in studies with small numbers of patients with cholangiocarcinoma/gallbladder cancer,^{71,72} and should be investigated in larger, controlled studies. Of patients, 58.8% (241 of 410) had involvement of the bile ducts in this study; 19.5% (80 of 410) had intrahepatic disease; 17.8% (73 of 410) had intrahepatic involvement; and 13.9% (57 of 410) had hilar disease. Survival benefit was most prominent in the intrahepatic group on a subgroup analysis (HR, 0.57; 95% CI, 0.34 to 0.94). The subgroup analyses were not powered to demonstrate benefit within each subgroup and, as such, should be viewed as hypothesis generating. Response rate was 19% versus 11.7% in the subgroup comprising both biliary and ampullary cancers.

At a conceptual level, there is support for the consideration of combined modality chemoradiation therapy for patients with unresectable disease using gemcitabine- or fluoropyrimidine-based strategies, and efficacy has been observed in small studies.^{73,74} However, definitive data through controlled trials remains unavailable and, as such, this remains an area of active investigation, particularly from the standpoint of patient selection and advantages over chemotherapy alone.

The advent of molecular profiling has uncovered putative therapeutic targets, which include aberrations in the *Akt-PI3K*-mammalian target of rapamycin (*mTOR*), Fanconi, *IDH1/2*, *ERBB-MEK*, and fibroblast growth factor receptor (*FGFR*) pathways.^{43,75,76} Fusions in fused in glioblastoma–repressor of silencing 1 (*FIG-ROS1*) and various *FGFR2* fusions such as *FGFR2-BICC* and others have been identified, and more such events will be identified with the increasing use of genomic sequencing studies. The pursuit of these targets may lead to an eventual individualized and heterogeneous approach to patients with both refractory and untreated disease in lieu of empiric approaches such as gemcitabine and cisplatin.

Perihilar Cholangiocarcinoma

pCCAs are cancers that arise from the extrahepatic biliary tract from the second order ducts to the origin of the cystic duct. These cancers are amongst the commonest malignancies of the biliary tract encountered in many parts of the world.

pCCAs should be distinguished from nonhilar, distal extracelular tumors because of their distinctive clinical presentations, natural history, staging, and management approaches. Although distinctive molecular and pathologic differences have yet to be determined, and the pathogenesis of these tumors may be similar, dCCAs are far less common than pCCAs and have better treatment outcomes. The reason for the predilection of pCCAs to predominantly arise at the liver hilum is not known.

Tumors that cause ductal obstruction at the hilar region are occasionally referred to as Klatskin tumors. However, the series reported in the classical paper by Klatskin included both intrahepatic and extrahepatic cancers, and was reported in an era in which the biliary tract was inaccessible to noninvasive preoperative imaging.⁷⁷ Thus, use of the term *Klatskin tumor* to describe pCCAs is inaccurate, confusing, and best avoided.

Diagnosis

Patients with early-stage cancers are often asymptomatic. Most patients present with painless jaundice and its clinical sequelae of dark urine, light stool, and pruritus. Nonspecific gastrointestinal symptoms such as anorexia and nausea, as well as mild weight loss and fatigue are not unusual. Most patients will present with painless obstructive jaundice, associated with pruritus, abdominal pain, weight loss (30% to 50%), and fever in about 20%.⁷⁸ The clinical presentation of pCCAs are indistinguishable from other malignancies causing large bile ductal obstruction such as dCCAs or pancreatic cancer. Obstruction of the bile duct and biliary stasis may lead to bacterial colonization and cholangitis, particularly in patients with biliary stones. Patients with cholangitis can present with high fever, pain, nausea, vomiting, and rigors.

Serum biochemical tests will reveal the evidence of cholestasis with elevations in bilirubin, alkaline phosphatase, and γ -glutamyltransferase. Serum aminotransferase levels may be normal or mildly elevated in the early stages. Serum CEA and CA19-9 levels are the most commonly elevated serum tumor markers. CA19-9 has limited value because levels can be elevated in benign biliary tract disease, cholangitis, or cholestasis. CA19-9 levels above 100 U/mL were found to be 89% sensitive and 86% specific for the diagnosis of malignancy in patients with PSC.^{79,80} CEA levels also have a low predictive value for cancer and are not helpful for a diagnosis.^{79,81} Both CA19-9 and CEA levels may be elevated in bile specimens in the presence of cancer.⁸² A combined index of CA19-9 and CEA has been proposed, with studies showing mixed results in predicting cancer. The presence of cholangitis or hepatolithiasis can cause elevations of tumor markers, and these tests should be repeated after symptoms have resolved. CA19-9 is a carbohydrate cell–surface antigen related to Lewis blood group antigens. Patients with a negative Lewis blood group antigen (representing 10% of the population) cannot synthesize

CA19-9 and will not manifest an elevation in this marker. Additional potential markers for CCA include CA242, CA72-4, CA50, CA125, RCAS1, and serum *MUC5AC*. These have all been evaluated with mixed results.^{80,83–87} CA19-9 has also been defined as a poor prognostic factor in CCA.⁸⁸

A diagnosis is usually based on history, cholangiography and cytology, or tissue analysis. pCCAs often arise and can progress to obstruction of one of the main bile ducts at the hilum before involving the other main duct. Unilateral obstruction of either the right or left bile duct alone may not lead to jaundice or an elevated bilirubin because of compensation from the normally draining lobe of the liver. However, the alkaline phosphatase and γ -glutamyltransferase may be elevated. Jaundice may occur when the tumor extends down the bile ducts to involve the confluence of the right and left ducts. Unilateral obstruction results in atrophy of the affected side of the liver and hypertrophy of the other side. This atrophy–hypertrophy phenomenon will also occur if the portal vein has also been blocked by the tumor. Because atrophy–hypertrophy results in an axial rotation of structures in the hepatoduodenal ligament, its effects need to be considered when interpreting imaging studies or in planning hepatic resections.⁸⁹

Any patient who has a perihilar stricture, without evidence of ductal disease elsewhere in the biliary tree suggestive of PSC, and who has not had previous biliary surgery that might have resulted in stricture, is considered to have pCCA. The diagnosis and evaluation of these tumors depends on the available diagnostic technologies and expertise. The goals are to (1) ascertain the nature and extent of obstruction, (2) obtain tissue for diagnosis if possible, and (3) stage the tumor to determine spread and metastasis to guide therapy. An abdominal ultrasound will confirm the presence of a biliary obstruction. Additional testing with either a CT or MRI/magnetic resonance cholangiopancreatography (MRCP) is needed to identify the potential and for staging if a malignancy is suspected. The accuracy of CT and MRI/MRCP for the prediction of the extent of ductal involvement ranges from 84% to 91%; for hepatic arterial invasion, it ranges from 83% to 93%; for portal vein invasion, from 86% to 98%, and for lymph node metastasis, from 74% to 84%.^{90–92}

Biliary tract imaging (cholangiography) with cytology is used to establish the diagnosis. Tissue biopsies can be obtained under fluoroscopic guidance, or using cholangioscopy during endoscopic retrograde cholangiopancreatography (ERCP). A cholangioscopy may allow for direct visualization, but often provides a lower amount of tissue for analysis.^{93–96} In one study, direct visualization for biliary strictures using a miniendoscope identified malignancy in 11 of 20 patients and resulted in modification of diagnosis of biliary stricture in 20 of 29 patients.⁹⁷

Peroral cholangioscopy using the spyglass system may also be associated with a higher rate of cholangitis. Confocal laser endomicroscopy is an emerging technique that may be helpful. Specific criteria (Miami criteria) for the diagnosis of a malignancy within a stricture using this technique have been proposed, but need to be further validated, and the specificity needs to be improved.⁹⁸ An endoscopic ultrasound (EUS) with fine-needle aspiration (FNA) may also be helpful for a diagnosis or to predict unresectability by detecting nodal spread. An intraductal ultrasound performed using an ultrasound probe passed into the common bile duct increased the accuracy of ERCP from 58% to 90%.⁹⁹

pCCAs are less accessible than other distal CCAs for sampling. The highly desmoplastic nature of these tumors further limits the amount of cellular material that may be obtained for a cytologic analysis. As a result, establishing a tissue diagnosis of pCCA is extremely difficult. The diagnostic sensitivity of tissue or cytology examination remains poor. Indeed, benign disease has been noted in about 10% of surgical resections performed for presumed pCCAs.^{100–102} A positive diagnosis with brush cytology ranges from 44% to 80%,^{103–105} with pooled data from over 800 CCA patients reporting a sensitivity of 42%, a specificity of 98%, and a positive predictive value (PPV) of 98% among patients with confirmed cancer.¹⁰³ A brush cytology is diagnostic and very useful when posi-

tive, but of little value when negative. In a study of 74 patients with pancreaticobiliary strictures, the sensitivity and specificity of brush cytology were 56% and 100%, respectively, and the positive predictive value was 100%.¹⁰⁶ Intraductal tissue biopsies also have a low diagnostic yield with a pooled sensitivity of 56%, a specificity of 97%, and a PPV of 97%. The use of multiple sampling techniques should be considered to improve the diagnostic yield of sampling.

Mucobilia on ERCP is an uncommon finding that is highly suggestive of a papillary CCA. Papillary tumors could be either intrahepatic or extrahepatic. FNA is also useful if a mass can be seen on ultrasound examination or on CT scan.

Staging

Disease staging in pCCA requires an assessment of the extent of ductal involvement as well as the extent of involvement of the liver parenchyma, lymph nodes, and vasculature and distant metastases.¹⁰⁷ The TNM system (Table 53.2) does not help to define surgical resectability and, therefore, may not adequately predict outcome.⁵¹ A classification for hilar tumors was introduced and modified by Bismuth.¹⁰⁸ This classification is based on the level of ductal involvement by the tumor, and provides a guide as to the extent of surgical resection that may be required for tumor eradication. However, it is not a true staging system and has low accuracy.¹⁰⁹ A registry of pCCA has been initiated to collect data that may serve as a resource to guide the development of meaningful future staging classifications.¹¹⁰

Management

A suggested approach to the management of pCCA is presented in Figure 53.2. The local extent of the disease along the biliary tree can be determined by direct or imaging-defined cholangiography—either ERCP, magnetic resonance cholangiography MRCP or percutaneous transhepatic cholangiography (PTC). However, the extent of disease may not be appreciated because of tumor spread along the wall of the bile duct without luminal compromise. PTC or MRCP may be more useful than ERCP in establishing the upper extent of disease. MRCP is less invasive, but may need to be supplemented with direct cholangiography at times. Vascular invasion has been assessed by MRI/MR angiography, angiography, or Doppler ultrasound. An MRI is useful to assess liver invasion or vascular involvement not clearly identified on CT scans. CT scans or MR angiography are replacing the need for an invasive angiography to assess vascular involvement. Color-flow Doppler ultrasound is very dependent on the operator, but can be effective at evaluating portal vein involvement and, in some cases, hepatic artery involvement.¹¹¹ Positron-emission tomography (PET)/CT scans, intraductal ultrasound (US), and EUS have all been used for staging. EUS with FNA may also be helpful for a diagnosis by detecting distal lymph node involvement. A staging laparoscopy with or without ultrasound can identify tumor spread beyond that detected on cholangiography, vascular encasement, or lymph node involvement.

Liver Transplantation. Liver transplantation has emerged as a viable option for the treatment of early stage, unresectable pCCA in highly selected patients.¹¹² For patients with tumors that are unresectable, a complete hepatectomy with liver transplantation may provide the only chance for a cure. The presence of extrahepatic nodal disease or metastases is a contraindication to transplant. In carefully selected patients, a multimodality approach combining preoperative chemoradiation, staging laparoscopy, and orthotopic liver transplantation has resulted in overall 5-year survival rates of up to 82%. A study of the combined experience of several centers showed an overall survival of 53% on an intention-to-treat analysis, with a 65% recurrence-free survival after 5 years.¹¹² It should be noted that these data reflect results obtained with a highly selected group of patients.

The availability of adequate organs for transplantation has limited the use of liver transplantation as a treatment modal-

TABLE 53.2

American Joint Committee on Cancer TNM Staging System for Perihilar Cholangiocarcinoma

Primary Tumor (T)			
TX	Primary tumor cannot be assessed		
T0	No evidence of primary tumor		
Tis	Carcinoma in situ		
T1	Tumor confined to the bile duct, with extension up to the muscle layer or fibrous tissue		
T2a	Tumor invades beyond the wall of the bile duct to surrounding adipose tissue		
T2b	Tumor invades adjacent hepatic parenchyma		
T3	Tumor invades unilateral branches of the portal vein or hepatic artery		
T4	Tumor invades main portal vein or its branches bilaterally, or the common hepatic artery, or the second-order biliary radicals bilaterally, or unilateral second-order biliary radicals with contralateral portal vein or hepatic artery involvement		
Regional Lymph Nodes (N)			
NX	Regional lymph nodes cannot be assessed		
N0	No regional lymph node metastasis		
N1	Regional lymph node metastasis (including nodes along the cystic duct, common bile duct, hepatic artery, and portal vein)		
N2	Metastasis to periaortic, pericaval, superior mesenteric artery, and/or celiac artery lymph nodes		
Distant Metastasis (M)			
M0	No distant metastasis		
M1	Distant metastasis		
Anatomic Stage/Prognostic Groups			
Stage 0	Tis	N0	M0
Stage I	T1	N0	M0
Stage II	T2a-b	N0	M0
Stage IIIA	T3	N0	M0
Stage IIIB	T1-3	N1	M0
Stage IVA	T4	N0-1	M0
Stage IVB	Any T	N2	M0
	Any T	Any N	M1

ity for pCCA. The use of living donor liver transplantation may overcome some of the limitations of organ availability for this indication because 5-year survival after living donor living transplantation (LDLT) was 69% compared with 63% after deceased donor transplantation. The outcomes are better in patients with pCCAs arising in the setting of PSC, with a 72% 5-year survival compared with 51% in non-PSC patients. Furthermore, patients with pCCAs undergoing neoadjuvant chemoradiation and liver transplantation have a quality of life that is similar to those for patients undergoing transplantation for other indications.¹¹³ If liver transplantation is being considered as a treatment option, FNA of the hilar lesion by EUS should be avoided because of the risk of tumor seeding.

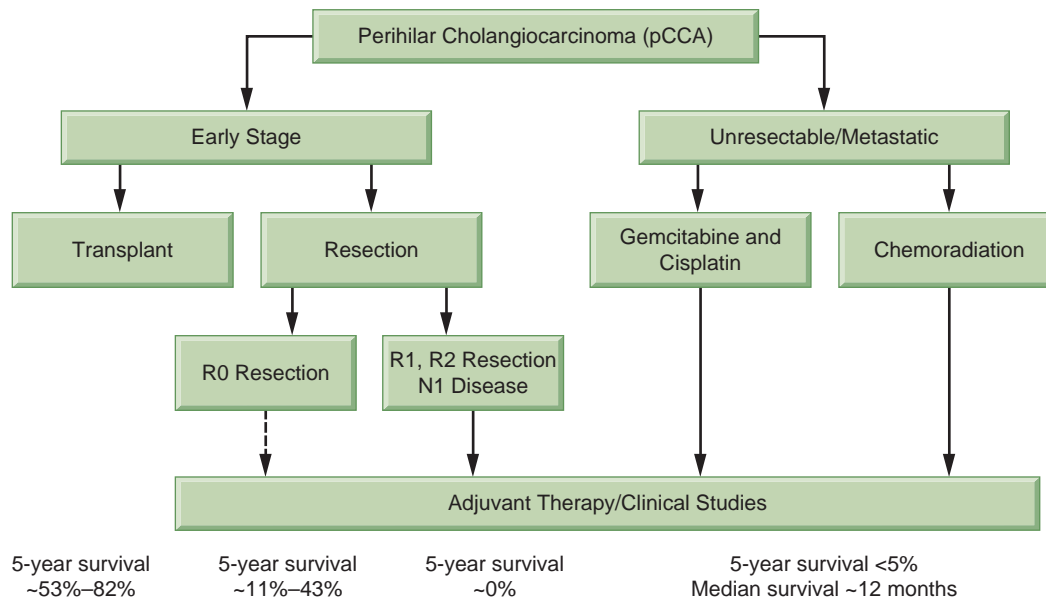

Figure 53.2 Algorithm for the management of perihilar cholangiocarcinoma.

In early reports, EBRT and bolus fluorouracil (5-FU), followed by brachytherapy, 5-FU, and liver transplantation, was used.^{114,115} Out of 28 patients, 11 were excluded because of metastatic disease found at the time of exploratory surgery. The rest underwent liver transplantation with an identifiable tumor noted on explant in 10 patients; 2 patients had recurrence after 40 months and 54 months, respectively; and 2 died of non-cancer-related causes. The median duration of follow-up was 41.8 months (range, 2.8 to 105.5 months); the 5-year actuarial survival rate for those transplanted was 87%. A follow-up protocol added a intrabiliary brachytherapy using iridium seeds after external beam radiation therapy (EBRT) and maintenance therapy with capecitabine until transplantation.¹¹⁵ Out of 56 enrolled patients, 28 received a transplant. The actuarial 1- and 5-year survivals were 88% and 82%, respectively, after transplantation. A similar protocol that combined neoadjuvant brachytherapy and infusional 5-FU followed by transplantation was reported, with 5 of 17 patients (29%) achieving long-term disease-free survival.⁹³ Other small series have demonstrated 3-year survival rates from 0% to 53%.¹¹⁶

Earlier studies of liver transplantation for patients with all types of CCA in unselected patients showed very poor results. Meyer et al.¹¹⁷ reported the results of liver transplantation for cholangiocarcinoma in 207 patients collected by the Cincinnati Transplant Tumor Registry. Fifty-one percent had recurrence, with a median time of recurrence of 9.7 months, and the median time between recurrence and death being 2 months. In a series of 7 patients undergoing liver-related transplant for CCA, 6 were alive after a median follow-up of 20 months. Recurrences were noted in all patients in this series with iCCA.¹¹⁸

Surgery. Surgical resection is complex and associated with mortality and morbidity. The results of surgical resection for pCCA have been reported in many retrospective single-institution surgical series. The goals of surgical resection are to remove the tumor with negative resection margins. An en bloc resection of at least one lobe of the liver, the extrahepatic bile duct, and a complete periportal lymphadenectomy may be required.

The preoperative assessment serves to define the extent of resection that may be required. There is a role for preoperative biliary drainage in some, but not all patients. This could be performed either percutaneously or endoscopically with stenting or placement of a nasobiliary tube. Biliary drainage can alleviate symptoms in patients with severe obstructive jaundice, renal

dysfunction, or pruritus.¹¹⁹ However, preoperative decompression can increase complications during or after surgery.^{120–123} Cholangitis may occur following bacterial colonization of bile and stenting may induce fibrosis, making it difficult to delineate the extent of tumor.¹²⁰ Five randomized trials and a meta-analysis have not demonstrated a benefit, although retrospective studies suggest a disadvantage to preoperative stenting.¹²⁴ It may be appropriate if a hemihepatectomy for CCA is planned in a jaundiced patient or if a pancreaticoduodenectomy is to be done in a patient with long-standing or severe jaundice. Other preoperative preparations include correcting a vitamin K deficiency and bowel preparation. The use of MRCP to guide decision making toward surgical resection may avoid the need for more invasive cholangiography and stenting.

Excision of the bile ducts may be possible up to the first order branches of the right and left bile ducts. If the tumor extends beyond this on one side, a partial hepatectomy may be needed, and a Roux-en-Y reconstruction performed. The contralateral preserved bile duct should be transected at the level of the first segmental branch to maximize the chance of a negative margin. If the resection is extended beyond the first order branches, a main drainage channel may need to be fashioned by suturing the individual segmental or sectoral ducts together. A caudate lobe resection is often routinely performed because invasion of the caudate ducts may occur. Several early branches of the left hepatic duct drain the caudate lobe and can be involved with the tumor involving the left main hepatic duct. Indeed, 46% of pCCAs microscopically involve the caudate lobe.^{125,126}

Surgery is indicated in the absence of distant metastases where a preoperative workup suggests that an R0 resection is feasible. Bilateral biliary involvement to the point that all four sectional ducts are involved precludes curative resection.¹²⁷ Other indicators of unresectability include bilateral intrahepatic bile duct spread, involvement of the main trunk of the portal vein, involvement of both branches of the portal vein or bilateral involvement of the hepatic artery and portal vein, or a combination of vascular involvement on one side of the liver with extensive bile duct involvement on the other side.⁸⁹ With vascular replacement, it may be possible to resect some tumors previously considered unresectable.

A periportal lymphadenopathy is not a contraindication, and resection with microscopic positive margins (R1) determined after resection can provide significant palliation. A lymphadenectomy should include all soft tissue in the porta hepatis, excluding the

portal vein and hepatic artery. The common hepatic artery nodes, the celiac artery nodes, the peripancreatic nodes, and the interaortocaval lymph nodes should be assessed because dissection may be indicated. Adequate staging may require sampling of at least seven nodes.¹²⁸

Resectable disease is present in approximately one-third of patients with suspected pCCA. In a series from 2001 to 2008, of 118 patients referred for surgery, 51% were resectable and 41% underwent R0 resection.¹²⁹ Operative mortality averaged about 8%¹³⁰; 5-year survival rates after resection have ranged from 10% to 35%. The results of surgical resection highly depend on whether negative resection margins are achieved.^{107,131–135} Frozen sections are used to evaluate tumor margins at the time of surgery and to guide the extent of resection. However, the desmoplastic nature of these tumors and fibroinflammatory changes related to the presence of a biliary stent, often restricts an accurate determination of the presence of a tumor in frozen sections.

When negative margins are obtained, median survival of patients with a tumor-free margin is ~3.4 years with a 5-year survival rate from 11% to 43%. However, when margins are positive, median survival is 1 to 1.2 years and 5-year survival is almost zero.^{107,132,135,136} With positive microscopic margins, there were no 5-year survivors in one study.¹³⁷ Other negative prognostic variables include tumor stage, nodal disease, tumor grade, bilirubin concentration, serum albumin level, postoperative sepsis, and absence of mucobilia.^{119,135,136,138,139} Recurrences most commonly occur locally at the resection bed or within the retroperitoneal lymph nodes. Distant metastases occur in one-third of cases, most commonly within the lung, mediastinum, liver, or peritoneum. Improved outcomes seen in more recent series may reflect increasing use of routine liver resections.

There are no established guidelines for surveillance and follow-up after surgical resection. There is high risk of recurrence, with peritoneal spread, hepatic metastases, local extrahepatic recurrence, and distant metastases (most commonly lung). Laboratory and radiologic evaluations every 3 months for the first 2 years after surgery and at longer 6-month intervals thereafter could be considered based on the perceived risk. The role of CA19-9 as a surveillance indicator is not established, but persistently rising levels may precede radiologic evidence of recurrence. The role of CT scans or MRI for surveillance and detection of tumor recurrence has not been evaluated in clinical trials. MRIs may be preferable to CT scans for surveillance because of the ability to concomitantly visualize the biliary tract. In a recent study, PET/CT scans demonstrated a higher positive predictive value compared to CT scans alone (94% versus 78%) for nodal metastases and a higher sensitivity (95% versus 63%) for distant metastases.¹⁴⁰ Surgery is generally not indicated for recurrent CCA. Close surveillance and early diagnosis of recurrences may allow for eligibility for clinical trials.

Adjuvant Therapy. There is a lack of conclusive data regarding the efficacy of adjuvant radiation therapy or chemoradiation therapy for patients who have a gross residual tumor, a tumor involving the resection margins, or regional lymph nodes involved with a tumor after undergoing resection with curative intent. The reported series have been small with the potential for selection bias, and there are no randomized trials that support any particular adjuvant approaches as standard. There is a need to explore and effectively evaluate new regimens for adjuvant therapy in these patients. It is recommended that patients are enrolled in clinical trials to define the role of adjuvant therapy. Similarly, there is a paucity of data upon which to base decisions on the use of adjuvant chemotherapy. In a randomized study, mitomycin C and 5-FU were compared with observation alone in a study of 508 patients with resected pancreaticobiliary cancers that included 139 patients with bile duct cancers.¹⁴¹ No apparent differences in overall or 5-year disease-free survival were noted. A phase III study comparing adjuvant capecitabine versus observation

alone in surgically resected patients has completed enrollment in the United Kingdom and outcomes data are eagerly awaited (NCT00363584). The primary endpoint of this study is 2-year overall survival. An analogous phase III study using gemcitabine in combination with oxaliplatin versus observation alone is underway in France with disease-free survival as the primary endpoint (NCT01313377). Data from these two pivotal studies will help define the role of adjuvant therapy more definitively. In the interim, the recommendation for patients is to participate in clinical trials whenever feasible.

Palliative Care. For unresectable tumors, palliation may be performed by percutaneous or endoscopic stent placement or by surgical bypass.

Stent Placement. The goal is to drain the most functional lobe of the liver with a stent that traverses the malignant obstruction and allows for internal drainage. Percutaneous biliary drainage is more appropriate for the drainage of intrahepatic ducts and may be required for access to these ducts. Both internal and external biliary drainage are possible. Both plastic or metallic stents may be used, with one study reporting a longer survival and lower complication rates with the latter.¹⁴² Biliary catheters may exit the skin and remain capped. This allows for irrigation and provides easy access for cholangiography and stent changes as needed. However, percutaneous draining catheters may decrease quality of life. An attempt should be made to enable the drainage of greater than 50% of more of the liver volume, irrespective of whether one or more stents are used or one or more segments are drained. Imaging-based volumetric assessments may be useful to determine whether drainage will be adequate. A guided approach using MRCP may be beneficial to routine bilateral stenting. If bilateral stents are placed, they may be used side by side or by contralateral stenting through the mesh of the first stent (stent in stent). Plastic stents typically clog within 2 to 6 months, whereas metal stents last longer, up to 8 to 10 months. Endoscopic metallic stenting should be performed by an experienced biliary endoscopist. Catheter tract recurrence is a rare complication of PTC-placed stents, and was reported in 6 of 441 patients (2.6%) who underwent percutaneous biliary drainage for pCCAs.¹⁴³ Patients with catheter tract recurrence had a lower survival than those without recurrence (17.5 months versus 23.0 months; $p = 0.089$).

Surgery. Surgical approaches have not been shown to be superior to percutaneous or endoscopic biliary drainage. A surgical bypass may avoid the need for long-term biliary tube placement, and its associated morbidity, such as cholangitis, occlusion, and need for frequent replacement. The disadvantage of surgical bypass for palliation is the morbidity associated with the procedure when there is limited overall life expectancy. If advanced unresectable disease is encountered at the time of a laparotomy for presumed resectable tumors, a bypass could be performed for palliation to avoid the need for another procedure. A surgical bypass for pCCA involving a bypass to intraparenchymal ducts using a defunctionalized limb of jejunum can be technically challenging but quite effective for palliation. A surgical biliary enteric bypass to segment III (Bismuth–Corlette cholangiojejunostomy), where the bile duct is accessed through the liver parenchyma anteriorly avoids the hilar region that may be involved with the tumor.¹⁴⁴ A bypass to right-sided ducts may be challenging.^{145,146} The right lobe could be drained by a bypass to the anterior sectoral bile duct. Surgical implantation of large-bore tubes through the tumor has been used in the past but is rarely employed now.

Photodynamic Therapy. Photodynamic therapy with stenting has shown to improve survival, reduce cholestasis, and improve quality of life compared to stenting alone in a randomized study.^{147–149} In a small, multicentered, randomized controlled trial of 39 patients, patients who received photodynamic therapy with

biliary stenting survived 493 days compared with 98 days for those treated with stenting alone.¹⁴² In a recently published meta-analysis of 6 studies, 170 patients received photodynamic therapy and were compared with 157 who had biliary stenting alone.¹⁵⁰ There were statistical improvements in patient survival and performance status, and a trend in the decline of serum bilirubin was significantly improved and the risk of biliary sepsis was similar (15%). These data also suggest a possible role for photodynamic therapy in these patients.

Radiation Therapy. There are very few data regarding the efficacy of the use of radiation therapy either alone or in combination with other techniques for advanced stage disease, either unresectable or resected with gross residual tumor. Most of the reported series are small and no randomized comparisons exist. Long-term survivors have been rarely described.

External-beam irradiation was successful in clearing jaundice in 10 of 11 patients in a recent report; no other decompressive measures were used.¹⁵¹ Brachytherapy has been applied through percutaneous tubes, with a median survival of 23 months.¹⁵² The combination of surgery and radiotherapy was reported to provide a median survival of 14 months in unresectable or recurrent disease.¹⁵³ However, other series have reported no benefit with radiation.¹⁵⁴ Stereotactic body radiotherapy (SBRT) may have some efficacy but has the potential for severe toxicity. In a study of 27 patients (26 with pCCA and 1 with iCCA), of whom 18 were treated on a prospective phase II trial and received 45 Gy in three fractions over 5 to 8 days,¹⁵⁵ the median overall survival was 10.6 months and the local control at 1 year was 84% with a median follow-up of 5.4 years. Six patients had severe duodenal or pyloric ulceration, and three patients developed duodenal stenosis. Interestingly, no such toxicity was observed in another group of 13 patients with Klatskin tumors.¹⁵⁶ Eight of these received 48 Gy in four fractions and the others received a range of doses (32 to 56 Gy in 3 to 4 Gy per fraction), and median survival was 33.5 months.

No formal comparative studies have been performed, although the median survival of 1 year observed with radiation therapy appears to be superior to 3 months with chemotherapy or 6 months with best supportive care alone.

Other Approaches. Endobiliary radiofrequency ablation may potentially provide benefits that are similar to the use of photodynamic therapy for palliation of malignant ductal obstruction, but the experience with this has been limited.¹⁵⁷ EUS-guided biliary drainage through a transgastric approach is technically feasible, but has high complication rates, such as bile leakage and peritonitis (20%) even in experienced hands.¹⁵⁸⁻¹⁶²

Systemic Therapy. As described earlier, based on the UK-ABC-02 data, gemcitabine and cisplatin should be regarded as the standard of care for patients with perihilar cholangiocarcinoma with unresectable disease. Although fluoropyrimidine-based therapies have shown evidence of preliminary efficacy, the role of subsequent lines of systemic chemotherapy remains to be definitively defined. Similarly, molecular profiling of these cancers may eventually result in a paradigm shift, allowing for the individualized treatment of patients based on single-agent/combination therapy based on perturbation of aberrant pathways.

Distal Cholangiocarcinoma

dCCAs are cancers arising from the extrahepatic common hepatic duct between the junction of the cystic duct and the papilla, but not involving either the cystic duct or the ampulla of Vater.

There is heterogeneity of cancers that arise from the extrahepatic bile duct. Other cancers that arise from the extrahepatic ducts but are considered separately from dCCAs include tumors

at the liver hilum or cystic duct. Cancers arising at the hilum are considered separately as pCCAs, whereas those arising within the cystic duct are considered along with other gallbladder cancers.

Diagnosis

The typical presentation of dCCAs is with obstructive jaundice. In the case of tumors arising below the insertion of the cystic duct, the gallbladder may be palpable. The presentation is similar to that of pCCAs or cancers arising from the head of the pancreas. Patients may present with jaundice associated with pruritus, weight loss, fever, and occasionally, with abdominal pain. Cholangitis may occur, but is rare as a presenting symptom in the absence of prior interventions directed toward the biliary tract such as cannulation or stent placement. Bile is sterile, but can serve as a medium for bacterial growth and can become contaminated with instrumentation. Patients with cholangitis may present with fever, abdominal pain, nausea, vomiting, and rigors. Bacteremia with biliary tract flora such as *Escherichia coli*, *Klebsiella*, *Proteus*, *Pseudomonas aeruginosa*, *Serratia*, *Streptococcus*, and *Enterobacter* may be present.

The presence of obstructive jaundice is an indication for further diagnostic testing to evaluate for malignant obstruction resulting from tumors of the bile ducts.

Laboratory tests suggest extrahepatic biliary obstruction with elevations in serum bilirubin, alkaline phosphatase, and γ -glutamyltransferase levels. Transaminase levels may be elevated, but typically to a lesser level.

Tumor markers may not be very helpful. CA19-9 has low accuracy for diagnosis because the levels may be increased in the presence of pancreatic cancer, or in the presence of cholangitis or biliary obstruction from other causes. In patients with PSC, a cutoff of 100 IU has a sensitivity of 89% and specificity of 86% for CCA in PSC.¹⁶³ The King's College group index that incorporates both CEA and CA19-9 values has attained similar sensitivities for cancer arising in patients with PSC.¹⁶⁴ Bile CEA levels are reportedly elevated in CCA, but not in benign diseases, other than intrahepatic stones.¹³⁸

Evaluation involves abdominal US, and body imaging with CT scans or MRI, as well as biliary tract imaging with ERCP. US is cheap, noninvasive, and is the best initial test for the detection of biliary stones or for ductal dilation that can occur with long-standing obstruction. Abdominal imaging with either a CT scan or MRI should be obtained for the patient with painless jaundice in whom malignancy is suspected. The advantage of MRI is that an MRCP could also be performed at the same time. Although a CT scan can identify mass lesions, an ERCP or MRCP may be needed to evaluate for the site and nature of biliary obstruction if no mass lesions are noted.

In patients without PSC and with no visible mass lesions, the presence of a single stricture by ERCP indicates a malignancy. In patients with PSC, a malignancy may be associated with the deterioration of clinical status and liver function tests. However, dCCAs may also present in these patients without any change in liver biochemistries. There are no data to determine the efficacy, timing, or effectiveness of screening and surveillance for a malignancy in patients with PSC, although this is often done in clinical practice using CT scans or an MRI/MRCP, with CA19-9.¹⁶⁴ The diagnosis of malignancy in patients who have a biliary tract stricture can be very difficult. Because of the dense associated stroma, well-differentiated cancers with little invasion are difficult to differentiate from the bile duct that has a fibrotic scar or stricture from PSC or other prior biliary injury. The presence of malignant-appearing cells within nerve sheaths (perineural invasion) is an important diagnostic criterion of malignancy that is not present in a benign stricturing disease such as PSC.

The differential diagnosis includes any cause of painless obstructive jaundice such as choledocholithiasis, pCCA, or pancreatic

cancer. As with pCCA, dCCAs must be differentiated from benign fibroinflammatory strictures such as from immunoglobulin (Ig) G4 cholangiopathy or sclerosing cholangitis.¹⁶⁵ The former can occur in the extrahepatic and intrahepatic ducts and is diagnosed by an elevated IgG4 in the serum, or by an increased number of IgG4-positive cells in tissue samples. The failure to consider these diagnoses may lead to inappropriate therapies, such as long-term stenting or hepatic resection, and these strictures may respond to corticosteroids.

Cancers of the lower bile ducts may not be readily distinguished from ampullary, duodenal, or pancreatic cancers. Although all of these cancers present in a similar manner to dCCA, establishing a diagnosis is helpful because dCCAs are less likely to metastasize widely and may have a more favorable outcome with aggressive treatment.

Staging

The AJCC's TNM system may be used for staging dCCAs (Table 53.3).⁶ Prior TNM staging systems did not consider separate staging systems for extrahepatic bile duct tumors. However, the seventh edition (2010) separated the staging of dCCAs from that of pCCAs. In order to determine resectability of the tumor, staging is necessary to identify the extent of tumor spread and the relationship to portal vein and superior mesenteric artery. EUS with FNA may be useful in determining the extent of tumor spread and involvement of local lymph nodes.¹⁶⁶ Although PET scanning for staging has been proposed, the benefit has not yet been shown.¹⁶⁷ A staging laparoscopy with or without US may enable the direct visualization of the peritoneal surfaces for metastatic implants, as well as detect vascular or nodal invasion, any of which would preclude resection for cure.^{127,168,169}

Management

An approach to the evaluation and management of the patient with suspected dCCA is presented in Figure 53.3.

Biliary Decompression. If the distal ducts are dilated and extending into the lower common bile duct, therapeutic decompression by ERCP or percutaneous stenting could be performed at the time of the initial evaluation. We recommend obtaining brushings at ERCP even if no masses have been seen on abdominal imaging studies.

Surgery. Surgical resection can be considered for locally confined dCCA without major vascular involvement or distant metastases. An intraoperative assessment with the help of the pathologist

TABLE 53.3

American Joint Committee on Cancer TNM Staging System for Distal Cholangiocarcinoma

Primary Tumor (T)

TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ
T1	Tumor confined to the bile duct histologically
T2	Tumor invades beyond the wall of the bile duct
T3	Tumor invades the gallbladder, pancreas, duodenum, or other adjacent organs without involvement of the celiac axis, or the superior mesenteric artery
T4	Tumor involves the celiac axis, or the superior mesenteric artery

Regional Lymph Nodes (N)

NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Regional lymph node metastasis

Distant Metastasis (M)

M0	No distant metastasis
M1	Distant metastasis

Anatomic Stage/Prognostic Groups

Stage 0	Tis	N0	M0
Stage IA	T1	N0	M0
Stage IB	T2	N0	M0
Stage IIA	T3	N0	M0
Stage IIB	T1	N1	M0
	T2	N1	M0
	T3	N1	M0
Stage III	T4	Any N	M0
Stage IV	Any T	Any N	M1

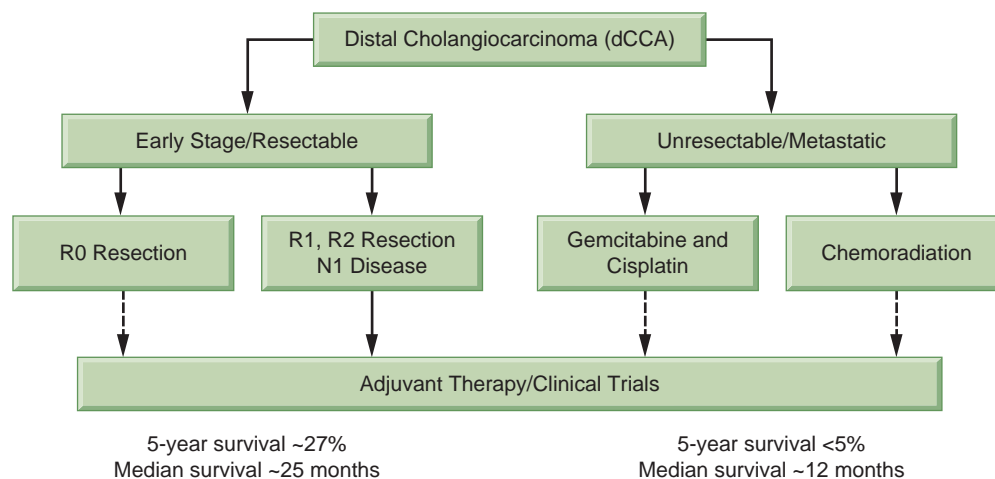

Figure 53.3 Algorithm for the management of distal cholangiocarcinoma.

must dictate the extent of resection. For localized dCCAs, a pancreaticoduodenectomy with resection of the extrahepatic bile duct to the level of the confluence may be required. Although dCCAs often involve the intrapancreatic portion of the common hepatic duct, on rare occasions the tumor may be confined to a small region of the duct and removed by an extrahepatic bile duct resection without a pancreaticoduodenectomy. The peripancreatic and periportal lymph nodes should be removed and examined, along with the interaortocaval lymph nodes, if necessary.

Although the incidence of dCCAs is lower than that of pCCAs, the resectability rate of dCCAs is much higher than that of pCCAs, which may contribute to improved outcomes. A pancreaticoduodenectomy with distal bile duct resection has a reasonable chance of providing a margin-negative resection for dCCAs. There is considerable morbidity and a mortality rate from 2% to 10%. Morbidity can arise from biliary fistulas in about 2% of patients or a fistula from the pancreatic–jejunal anastomosis in 5% to 10% of patients. Although many patients require pancreatic enzyme replacement after this procedure, few develop diabetes. Short-term outcomes and/or quality of life are similar between the pylorus-preserving and standard types of pancreaticoduodenectomy.^{170,171} Extensive en bloc–combined hepatic and pancreatic resections could be considered in the rare circumstance that there is extensive involvement of the entire bile duct without any evidence of distant spread. The morbidity of such extensive surgery is very high, and the overall prognosis is poor.¹²⁶ The 5-year survival rates after an R0 resection is 27%, with a median survival time of 25 months. The expected 5-year survival is between 23% and 50%. Prognostic factors for poor survival include high p53 expression, nodal metastases, positive margins, pancreatic invasion, and perineural invasion.^{172,173}

There are no established guidelines for surveillance and follow-up after surgical resection. Laboratory and radiologic surveillance modalities and intervals will be determined on perceived risk on an individual basis. Tumor recurrence may occur locally within the peritoneum or local nodes or with distant metastases.

Adjuvant Therapy. Postoperative adjuvant radiotherapy can be administered by intraoperative radiotherapy (IORT), EBRT, intrabiliary brachytherapy, or a combination of modalities. EBRT is widely available, noninvasive, and can deliver a homogeneous dose to a large volume. In most series, EBRT has been used to deliver a dose of 40 to 50 Gy (at 1.80 Gy per day) to the tumor bed and draining lymph node basin. In some series, a smaller volume (i.e., a boost) was treated with additional EBRT, intraluminal brachytherapy, or IORT to a total dose of 60 Gy or more. Most commonly, radiotherapy is administered in a continuous course during 5 to 6 weeks. However, the role of radiotherapy from an efficacy standpoint remains to be definitively ascertained. Similarly, as described earlier, the role of chemotherapy remains an area of active investigation in patients with biliary cancers.

Palliative Care. For unresectable dCCA, palliation by stenting for biliary decompression by itself, or in combination with chemotherapy may be considered. Plastic or metal stent placement can be performed at the time of ERCP or PTC, and an internal or external drainage. In general, replaceable plastic stents are used for those with a life expectancy of less than 6 months, and metal stents are used for those with a longer life expectancy, based on results of a randomized controlled trial.¹⁷⁴ Plastic stents need to be replaced every 3 months for best results and to minimize cholangitis. This requires repeated endoscopy procedures. Metal expandable stents remain patent for a longer time and are associated with less cholangitis, but they cannot be readily removed. Tumor advancement may lead to a complete stent occlusion.

A randomized trial of surgical bypass versus endoscopic intubation favored the latter.¹⁷⁵ Unresectability can often be determined preoperatively, but if unresectability is determined only at the time of an open exploration, a palliative bypass for biliary

decompression and jejunal bypass may be performed. A surgical bypass to the common bile duct does involve the morbidity associated with laparotomy and bowel anastomosis. A laparoscopic bypass of a distal bile duct obstruction can be performed,¹⁴⁵ usually with a cholecystojejunostomy. This will be unsuccessful if the common bile duct at the level of the cystic duct is involved with the tumor.

The efficacy of radiation therapy for advanced unresectable disease has never been evaluated in prospective randomized trials. Radiation therapy can result in biliary tract and intestinal complications. The available data is based on small retrospective reviews with heterogeneous patient populations that have been treated with a wide variety of modalities and techniques. As described earlier, based on the UK-ABC-02 data, gemcitabine and cisplatin should be regarded as the standard of care for patients with dCCA. Although fluoropyrimidine-based therapies have shown evidence of preliminary efficacy, the role of subsequent lines of systemic chemotherapy remains to be definitively defined. Similarly, molecular profiling of these cancers may eventually result in a paradigm shift, allowing for individualized treatment of patients based on single-agent/combination therapy predicated on the perturbation of aberrant pathways.

GALLBLADDER CANCER

Incidence and Etiology

Gallbladder cancers (GBC) are cancers that arise from the gallbladder mucosa. GBC is the fifth most common malignancy of the gastrointestinal tract. The incidence of GBC correlates with the prevalence of cholelithiasis. Patients who have gallstones for longer than 40 years have a significantly higher incidence of GBC than those who have had gallstones for a shorter time. It has been postulated that 1% of patients aged 65 years or more with gallstones would develop GBC, and this may reflect the duration of stone disease.¹⁷⁶ GBC affects women three to four times more often than men and is more common in Caucasians than in African Americans. The incidence of GBC increases with age, with the greatest incidence in persons aged 65 or more. However, there have been isolated reports of GBC diagnosed in children.^{177–179} Mortality trends have been variable. Germany and the Netherlands have relatively high mortality rates from GBC, but have shown declines in most age groups. Sweden, France, and Bulgaria show steady upward trends. In Japan, the incidence increased through the 1980s but has stabilized in recent years.¹⁸⁰ GBC incidence in the United States, Britain, and Canada has stabilized or declined. These changes have occurred coincident with the rise in the number of laparoscopic cholecystectomies.¹⁸¹

Geographic Variation

The incidence of GBC varies considerably with geographic location.²²⁴ In the United States, GBC is the most common cancer of the biliary tract, but is a rare cancer with an incidence of 1 to 2 per 100,000. A study based on data from the Surveillance, Epidemiology, and End Results (SEER) program reported an incidence of 1.2 cases per 100,000 population per year in the United States.¹⁸² The highest incidence of GBC occurs in Chileans and Bolivians.¹⁸³ Mortality from GBC in Chile is 5.2%, the highest in the world.¹⁸⁴ GBC is the main cause of death from cancer among women in Chile. The incidence of GBC is also high in Native American, Hispanic American, Latin American, Japanese, and Zimbabwean women,¹⁸⁵ and in Americans of Mexican origin.¹⁸⁶ Lower rates of GBC occur among Nigerians, New Zealand Maoris, and Chinese natives and immigrants.¹⁸⁵ Within the United States and the United Kingdom, urban areas show higher incidences than rural regions. It has been suggested that lower socioeconomic

status may lead to delayed access to cholecystectomy, which may increase GBC rates.¹⁸⁷

Ethnicity

There are considerable ethnic differences in the incidence of GBC. In contrast to the general population, the incidence of GBC is much higher in Native Americans in the Southwest United States and in Mexican Americans. In Mexico, the highest incidence of GBC is in *mestizos* (i.e., people of mixed ancestry). The incidence of GBC in Spain, Cuba, and Puerto Rico is low, suggesting that the geographic and ethnic variations noted in GBC incidence in North and South America may be related to Native American rather than Spanish heritage. In Bolivia, differences are related to tribal origin.¹⁸⁵

Risk Factors

Established risk factors include gallstone disease, bile composition, calcification of the gallbladder wall, congenital biliary cysts or ductal anatomy, some infections, environmental carcinogens, and drugs. Some of the noted geographic differences may reflect genetic differences. Although gallstone disease is associated with GBC, the mechanisms predisposing to this increased risk are not known. Cholelithiasis is present in 70% to 90% of patients with GBC, and the incidence of GBC in patients with cholelithiasis ranges from 0.5% to 3%.¹⁸⁸ The risk of GBC was increased in a prospective cohort study of patients with gallstones, although the incidence (9 per 10,000 per person-years), and the absolute number of cases of GBC (5 of 2,583 people) in this population was low.¹⁸⁹ The duration of gallstone disease, the patient age, the size of gallstones, and possible carcinogenic effects of gallstones, such as from the chemical composition or bacteria within the stones, may be important; although, in one study patients with cancers did not have larger stones, nor were their stones of higher cholesterol content.^{190,191}

Although familial clusters of GBC have been reported, an inherited predisposition has not been found in large series.¹⁹² A recent cohort study from Sweden found an association among first-degree relatives, specifically among parents (relative risk [RR], 5.1; 95% confidence interval [CI], 2.4 to 9.3) or offspring (RR, 4.1; 95% CI, 2.0 to 7.6).²³⁵ Genetic variants in DNA repair pathways may be involved in gallbladder carcinogenesis.¹⁹³

There is a high incidence of GBC in patients with an anomalous pancreatic-biliary duct junction (APBJ), and this risk is independent of the presence of gallstones. Studies from Japan have linked APBJ to other biliary tract cancers as well as GBC.¹⁹⁴ About 2% of Japanese patients examined had APBJ, with about 75% of these cases associated with a choledochal cyst and duct dilation. The rest were noted to have normal caliber bile ducts.^{194,195} Patients with APBJ get cancer at a younger age than patients with sporadic GBC. Children with APBJ frequently have epithelial hyperplasia of the gallbladder.¹⁹⁶

GBC has been associated with partial or complete calcification of the gallbladder wall (porcelain gallbladder). The association is controversial, with some studies reporting an incidence up to 25%, and other studies disputing the association.^{197,198}

Salmonella typhi carriage has been associated with GBC. Typhoid carriers may also suffer chronic inflammation of the gallbladder and have a sixfold higher risk of gallbladder cancer.¹⁹⁹ *Helicobacter bilis* and *Helicobacter pylori* have been identified in bile specimens and have been demonstrated to increase the risk of carcinoma by about sixfold.^{200,201}

Exposure to toxic environmental factors in the automotive, rubber, textile, and metal industries have been associated with GBC.^{183,190,202} Chemicals implicated in gallbladder carcinogenesis include methyldopa, oral contraceptives, isoniazid.^{203–205}

An elevated body mass index has been associated with GBC. Although many cohort studies have identified obesity as a risk factor for GBC, this parallels the risk for gallstone disease. Other rare

associations with gallbladder cancer include previous gastric surgery, inflammatory bowel disease, and polyposis coli.

Pathology

Sixty percent of GBCs occur in the fundus, 30% occur in the body, and 10% occur in the neck of the gallbladder. Tumors that arise in the neck and the Hartman pouch may infiltrate the cystic and common bile duct, making them clinically and radiographically indistinguishable from pCCAs. They may be isolated tumors or involve the gallbladder through intramural spread analogous to linitis plastica of the stomach. Gallbladder cancer can spread early by direct extension into the liver and other adjacent organs. This cancer also has a propensity to seed and grow in the peritoneal cavity, and along needle biopsy sites and in laparoscopic port sites. At autopsy, GBC patients have a 91% to 94% incidence of lymphatic metastasis, 65% to 82% have an incidence of hematogenous metastasis, and 60% have an incidence of peritoneal spread.^{206,207} Hematogenous metastasis tends to be from invasion into small veins that extend directly from the gallbladder into the portal venous system, leading to hepatic metastases in segments IV and V of the liver. There is a high propensity for intra-abdominal recurrence after resection, with distant metastasis occurring late in the course. The only common extra-abdominal site of metastasis is the lung. It is rare, however, to have metastasis to the lung in the absence of advanced local-regional disease.

GBC can be categorized into infiltrative, nodular, and papillary forms. The infiltrative tumors are the most common form and cause thickening and induration of the gallbladder wall, sometimes extending to involve the entire gallbladder. These tumors spread in a subserosal plane. Tumor seeding into the peritoneal cavity can occur if the subserosal plane is violated during and the presence of the tumor is not recognized at the time of cholecystectomy. Advanced tumors can invade the liver and can result in a thick wall of tumor encasing the gallbladder. Nodular or mass-forming GBCs can show early invasion through the gallbladder wall into the liver or neighboring structures. Despite this invasiveness, it may be easier to control surgically than the infiltrative form, where the margins are less defined. Papillary carcinomas exhibit a polypoid or cauliflowerlike appearance and fill the lumen of the gallbladder with only minimal invasion of the gallbladder wall. The prognosis of these tumor is better than other forms of GBC.

Most malignant neoplasms of the gallbladder are adenocarcinomas. Primary malignant mesenchymal tumors of the gallbladder have been described, including embryonal rhabdomyosarcoma, leiomyosarcoma, malignant fibrous histiocytoma, angiosarcoma, and Kaposi sarcoma. Other primary rare tumors of the gallbladder include carcinosarcomas, carcinoids, lymphomas, and melanomas. In addition, the gallbladder can be involved with metastatic cancers from numerous sites. Many tumors exhibit more than one histologic pattern. The only histologic type with clear prognostic significance is the papillary adenocarcinoma, which has a markedly improved survival compared with all other histologic types. There is also evidence to suggest that oat cell carcinomas, adenosquamous tumors, and carcinosarcomas have a poorer survival rate.²⁰⁸

Gallstones are found in more than 75% of all patients with GBC. In the presence of gallstones, chronic mucosal irritation predisposes one to malignant transformation. Cholesterol stones are the most common type associated with GBC. Bile from high endemic areas is more mutagenic than that from low endemic areas.²⁰⁹ Although the chemical composition of stones or bile may be related to the development of cancer, there are no conclusive data linking biliary bile acids to GBC. A potential mechanism of carcinogenesis may involve the excretion of dietary or chemical metabolites within bile, with bile acids acting as cocarcinogens. Experimentally, GBC was induced by the carcinogen dimethylnitrosamine in 68% of hamsters with cholesterol pellets inserted into the gallbladder compared to 6% of controls fed the carcinogen alone.²¹⁰ Calcification is the end stage of a long-standing

inflammatory process, and calcification of the gallbladder (porcelain gallbladder) is associated with cancer in 10% to 25% of cases. Despite this association, the incidence of GBC in patients with gallstones is only 0.3% to 3%.

Cancers arising from gallbladder mucosa behave similar to other adenocarcinomas of the gastrointestinal tract. Premalignant to invasive malignant changes can be found; metastatic spread occurs by lymphatic and vascular routes; the diagnosis is often delayed; and survival is related to the stage. Interestingly, at the population level, mortality is also inversely related to cholecystectomy rates.²¹¹ GBC originates as mucosal lesions and, as growth progresses, the tumor invades the wall of the gallbladder. The lack of a well-defined muscularis leads to early entry of invasive GBC into the perimuscular connective tissue. Lymphatic, neural, and hematogenous invasions occur earlier with GBC than with other cancers of the gut.

Adenocarcinomas progress from metaplasia–dysplasia to carcinoma in situ to cancer. Chronic inflammation may play a role in the development of premalignant lesions.²¹² Two types of metaplasia—intestinal and squamous—have been found in patients with GBC. The relation of intestinal metaplasia to the subsequent development of GBC has not been determined. Squamous metaplasia, in which squamous epithelium replaces the normal gallbladder epithelium, is a rare premalignant lesion associated with squamous cell cancer of the gallbladder. Cholecystitis follicularis, a rare type of inflammation, has been reported in a few cases of GBC, but its premalignant potential is unclear.²¹² Progression from dysplasia to carcinoma in situ to invasive cancer in the gallbladder epithelium can take about 15 years.²¹³ Dysplastic changes are found in adjacent mucosa in most GBCs. Gallbladder adenomas are rarely encountered or associated with dysplasia.

Several mutations have been reported in GBCs. *K-ras* and *p53* mutations are common.^{186,214} Mutant *p53* is found in 92% of invasive carcinomas, 86% of carcinoma in situ, and 28% of dysplastic epithelium, but not in adenomas.²¹⁵ *K-ras* mutations are identified in 39% of GBCs.²¹⁶ Data on the expression of *ras* and *myc* are conflicting. In one study, *b-RAF* mutations were evident in 33% of GBCs.²¹⁷ The *erbB2* oncoprotein is overexpressed in some patients with GBC, and transgenic mice that express *erbB2* in the gallbladder epithelium develop GBC. Activated *EGFR* and *c-MET* may occur.^{218,219} The fragile histidine triad (*FHIT*) gene is a candidate tumor suppressor gene in GBCs.²²⁰ Epigenetic inactivation of *SEMA3B* and *FHIT* occurs in some GBCs.²²¹

The malignant potential of APBJ is quite high and this anatomic variant is associated with premalignant histologic changes of epithelial hyperplasia with a papillary or villous appearance. The nonmalignant areas of the gallbladder of patients with APBJ-associated GBC show increased hyperplastic changes in the gallbladder mucosa compared with patients with sporadic GBCs.²²² In a cat model, side-to-side biliary–pancreatic anastomosis produced hyperplastic changes in the gallbladder within 6 months.²²³ Although *K-ras* mutations are not commonly observed in lesions associated with gallstones, they are frequently identified in dysplastic lesions associated with APBJ. The differences in presentation, morphology, and molecular changes indicate that there are at least two distinct pathways to gallbladder carcinogenesis associated with either stone disease or with APBJ.²²⁴

Prevention

The low incidence of GBCs in some countries may be related to the rate of cholecystectomy performed for gallstone disease. However, the prevention of GBCs is not considered as a sole indication to perform cholecystectomy in patients who have asymptomatic gallstones. The incidence of gallbladder cancer is low compared with the incidence of gallstones in the population.

In certain high-risk conditions involving abnormalities within the gallbladder wall, a prophylactic cholecystectomy could be considered. A calcified or porcelain gallbladder is an indication

for cholecystectomy in the asymptomatic patient, because up to 25% of cases will be associated with gallbladder cancer. Patients with pancreaticobiliary maljunction and a normal-sized bile duct may benefit from a prophylactic cholecystectomy.²²⁵ A study of northern Indian women reported a benefit of prophylactic cholecystectomy.²²⁶ A serum CA19-9 evaluation and bile cytology may be helpful in making a preoperative diagnosis of cancer. A laparoscopic cholecystectomy could be reserved for those with normal markers and negative cytology. For those highly suspicious of cancer, the laparoscopic approach is not reasonable because of the risk for inadvertent seeding of the peritoneal cavity.

Diagnosis

Patients with gallbladder cancer are often asymptomatic. When symptoms occur, they may be similar to biliary colic or chronic cholecystitis, and are nonspecific. In contrast to biliary colic, patients with GBCs may have diffuse abdominal pain of a more constant nature. As a result of the low index of suspicion, patients with gallbladder cancer present with symptoms at an advanced stage of disease, or as incidental findings at the time of imaging or cholecystectomy for unrelated reasons. Recent weight loss and persistent right upper quadrant pain should raise the suspicion of GBCs in elderly patients over 70 years of age.

In early stage disease, symptoms can mimic those of cholelithiasis and cholecystitis or they may be related to associated cholelithiasis. Pain may be dull and aching, colicky, sharp, constant, or intermittent, with radiation to the back and associated with nausea, vomiting, and anorexia. At more advanced stages, jaundice, weight loss, hepatomegaly, a palpable mass, or ascites may develop. Jaundice can result from the obstruction of extrahepatic bile ducts by direct tumor growth or from metastatic disease. Jaundice is a poor prognostic sign, and 85% of patients with jaundice have unresectable tumors.¹⁸⁸ Mirizzi syndrome, in which compression of the common hepatic duct results from an impacted stone in the gallbladder neck, can be a presentation of GBC. Rarely, duodenal or colonic obstruction, cholecystoenteric fistula, or evidence of extra-abdominal metastases such as palpable mass, ascites, or paraneoplastic syndromes such as acanthosis nigricans may occur. These indicate an advanced malignancy and unresectable disease.

Tumor spread can involve the liver and the extrahepatic biliary tree by direct spread. Liver metastases without full-thickness invasion of the gallbladder wall occurs in less than 10% of cases. Lymph node metastasis to the cystic, pericholedochal, peripancreatic, and celiac nodes occurs early, and are present at the time of diagnosis in more than half of patients. Direct invasion of the duodenum or colon, intraperitoneal spread, Krukenberg tumors (i.e., ovarian metastases), and hematogenous dissemination can also occur.³

Laboratory findings lack specificity and are not diagnostic. Patients may have increased alkaline phosphatase and bilirubin levels as a result of ductal obstruction in advanced cases. Serum CEA or CA19-9 may be elevated, but these tumor markers are not diagnostic. A CA19-9 level above 20 U/mL has a 79% sensitivity and a 79% specificity for the diagnosis of GBCs. A CEA greater than 4 ng/mL is 93% specific for GBCs, but sensitivity is only 50% for detecting cancer. CA125 has also been reported to be a reasonable marker for gallbladder cancer in some small studies.²²⁷

An ultrasound is the usual initial diagnostic study whenever gall bladder or biliary tract disease is suspected. Findings on ultrasonography of the gallbladder that are suggestive, but not diagnostic, of GBCs include thickening of the wall, a luminal mass, calcification, or a mass lesion. A comparison between patients with unsuspected GBCs and those with benign gallbladder disease found that a solitary stone or displaced stone, or an intraluminal or invasive mass were more commonly associated with cancer.²²⁸ On ultrasonography, a discontinuous gallbladder mucosa, echogenic mucosa, and submucosal echolucency were significantly more common in GBC than in benign gallbladder disease. A polypoid

mass was present in 27% and a gallbladder-replacing or invasive mass was present in 50% of cases of GBC examined.²²⁸

Mucosal thickening should be viewed with suspicion. US will detect polyps that may represent nonmalignant lesions such as adenomas, papillomas, or cholesterosis in addition to GBCs. An invasive cancer is more likely in polyps greater than 1 cm in diameter. The accuracy of US for staging disease extent or spread is low (38% in one study).²²⁹ EUS is useful for a further diagnosis of polyps or gallbladder wall thickening. EUS has a higher sensitivity (92% versus 54%) and specificity (88% versus 54%) for GBC than US. It can also enable FNA of any suspicious masses or aspiration of bile for cytology. If a tumor is present, EUS can be useful for staging by assessing tumor wall invasion or distant nodal spread.

Abdominal CT scans or MRI can identify intraluminal polyps, gallbladder wall thickening, mass lesions, hepatic involvement, nodal enlargement, or other distant spread. CT scanning will reveal a mass partially obliterating the gallbladder lumen, a polypoidal mass, or diffuse wall thickening. However, only one-third of pathologically positive nodes are identified preoperatively by CT scan. The use of MRI for the diagnostic workup of GBC can be helpful. MRCP may provide more detailed information than can be provided by US or CT scan.²³⁰ MRI may be helpful in determining vascular invasion and nodal involvement. There is almost no role for cholangiography using ERCP or PTC, although these may occasionally be needed to plan the extent of surgical resection by determining the extent of ductal involvement or spread.²³¹

Fluorodeoxyglucose (FDG)-PET scanning has low sensitivity for extrahepatic disease. However, PET scanning may identify a disease that has not been radiologically apparent and resulted in a change in stage and treatment in 17% to 23% of cases with presumed localized resectable disease in one study.⁶⁵ For suspicious lesions on US, PET scanning has been reported to have a sensitivity of 0.80 and a specificity of 0.82, a positive predictive value of 0.67, and a negative predictive value of 0.90.²³²

The need for tissue biopsy before definitive exploration and resection of a mass that is suspicious for GBC is controversial because of the risks of the tumor seeding into the peritoneal cavity or abdominal wound. Bile cytology may avoid these and should be performed whenever any patient suspected of having GBC who undergoes ERCP or PTC. The diagnostic accuracy of combined ERCP and bile cytology is 50% for gallbladder cancers. The sensitivity of bile cytology alone for the diagnosis of GBC has been reported between 50% and 73%.²³³ If referral for surgical management is being considered, a diagnosis based on bile cytology or percutaneous FNA cytology would be preferable to operative or laparoscopic biopsy.

Percutaneous FNA or core needle biopsy are indicated for unresectable masses. The risk of tumor seeding within the needle tract is greater with the latter. EUS-directed FNA for gallbladder lesions is associated with a 80% sensitivity and 100% specificity.²³⁴ Percutaneous FNA has an 88% accuracy for gallbladder cancers with a negligible false-positive rate.²³⁵ EUS may be useful to distinguish between inflammatory nodes and metastatic disease during an evaluation of periportal and peripancreatic adenopathy. A staging laparoscopy to determine the extent of spread may be helpful for some patients.^{127,169}

Survival of patients with GBC is related to stage and histologic type of cancer. Lymph node involvement is rare in stage T1 tumors^{235,236}; that is, lymph node involvement almost never occurs until the muscularis has been penetrated. After that, lymph node involvement is common, occurring in about 50% of stage II patients and in 70% to 80% of patients in stage III and IV. There is a close correlation between lymph node involvement and prognosis. Most long-term survivors are patients with well-differentiated tumors that were minimally invasive. These are usually found incidentally at or immediately after cholecystectomy.

GBCs may be identified incidentally at the time of cholecystectomy; the incidence ranges from 0.3% to 1%. If this occurs during a laparoscopic procedure, the potential for port-site

implantation should be considered,^{237,238} and the gallbladder is extracted in a plastic bag. Implantation can arise due to physical contact between the tumor and port site tissues during extraction, or can be related to positive-pressure pneumoperitoneum.²³⁹ The tissue surrounding the trocar ports is excised because seeding may have occurred. Early reoperation may be necessary if the tumor is discovered on later pathologic examination, or with uncertainty about residual tumor. Stage I gallbladder carcinomas with clear resection margins may not require further surgical treatment.

Gallbladder polyps may be malignant but are rarely so when they are smaller than 1 cm in diameter. In a series of patients with gallbladder polyps, none were malignant if less than 1 cm in diameter, but 23% of polyps larger than 1 cm were malignant.²⁴⁰ In another series, 88% of polyps larger than 1 cm in diameter were malignant, and polyps larger than 1.8 cm were more likely to contain a more advanced stage of cancer.²⁴¹ FNA is an accurate way of distinguishing between polyps due to cholesterosis and neoplastic polyps,²³⁵ especially for polyps that are larger than 1 cm in diameter²⁴²; however, it is much less accurate in determining whether a neoplastic polyp is an adenoma or carcinoma.²⁴² Doppler US imaging of blood flow within a neoplastic polyp may also be useful in distinguishing these lesions from benign polyps.

Staging

Several staging systems have been described for GBC. These systems incorporate clinical and pathologic characteristics with prognostic significance. These include the modified Nevin system, the Japanese Biliary Surgical Society system, and the AJCC TNM staging system.^{6,235,243} The use of these different staging systems makes it difficult to compare the treatment results of different series in the literature. The AJCC TNM staging system should be used for the standardization of reporting across studies so as to enable a comparison of treatment results. This staging system is shown in Table 53.4. Stage I includes tumors that invade the lamina propria or muscle layer. Tumors can arise in the Rokitsansky-Aschoff sinuses and are considered stage I in a subserosal position. Tumors with invasion into the perimuscular connective tissue are considered stage II, and liver invasion is stage III. Extensive nodal metastasis to periaortic, pericaval, superior mesenteric artery, or celiac artery is now considered stage IVA. Patients with distant metastasis are considered stage IVB. GBCs undergo histopathologic grading from G1 (well differentiated) to G4 (undifferentiated). Although the grade does not factor into staging, it has prognostic significance, with high-grade tumors having a worse prognosis.

Management

Most studies of treatment approaches for GBC are from small case series or are heterogenous studies that include other biliary tract cancers. As a result, the optimal approaches to surgery or palliative therapy with chemoradiation are unknown. The stage of the disease determines the treatment approach and prognosis.²³⁵ The diagnosis of GBC usually occurs at advanced stages TNM III or IV, and most patients in advanced stages are not resectable.^{244,245} A suggested management scheme is outlined in Figure 53.4.

Surgery. Surgery is the only potentially curative option for GBCs. Absolute contraindications to surgery include distant metastases, vascular involvement, or nodal spread beyond the hepatoduodenal ligament. When GBC is suspected, an open cholecystectomy is preferable to laparoscopic excision to minimize the potential impact of tumor implantation due to gallbladder perforation and bile spillage that are more frequent with the latter. An extraserosal cholecystectomy excises the gallbladder on a deeper plane than a standard cholecystectomy, so that the gallbladder and all connective tissue down to actual liver tissue are removed. The extent of resection will depend on the extent of disease spread. For T1 lesions where the tumor has not penetrated the muscularis mucosa and margins are negative, cholecystectomy is sufficient and can

TABLE 53.4

American Joint Committee on Cancer TNM Staging of Gallbladder Cancer

Primary Tumor (T)			
TX	Primary tumor cannot be assessed		
T0	No evidence of primary tumor		
Tis	Carcinoma in situ		
T1	Tumor invades lamina propria or muscular layer		
T1a	Tumor invades lamina propria		
T1b	Tumor invades muscular layer		
T2	Tumor invades perimuscular connective tissue; no extension beyond serosa or into liver		
T3	Tumor perforates the serosa (visceral peritoneum) and/or directly invades the liver and/or one other adjacent organ or structure, such as the stomach, duodenum, colon, pancreas, omentum, or extrahepatic bile ducts		
T4	Tumor invades main portal vein or hepatic artery or invades two or more extrahepatic organs or structures		
Regional Lymph Nodes (N)			
NX	Regional lymph nodes cannot be assessed		
N0	No regional lymph node metastasis		
N1	Metastases to nodes along the cystic duct, common bile duct, hepatic artery, and/or portal vein		
N2	Metastases to periaortic, pericaval, superior mesenteric artery, and/or celiac artery lymph nodes		
Distant Metastasis (M)			
M0	No distant metastasis		
M1	Distant metastasis		
Anatomic Stage/Prognostic Groups			
Stage 0	Tis	N0	M0
Stage I	T1	N0	M0
Stage II	T2	N0	M0
Stage IIIA	T3	N0	M0
Stage IIIB	T1–3	N1	M0
Stage IVA	T4	N0–1	M0
Stage IVB	Any T	N2	M0
	Any T	Any N	M1

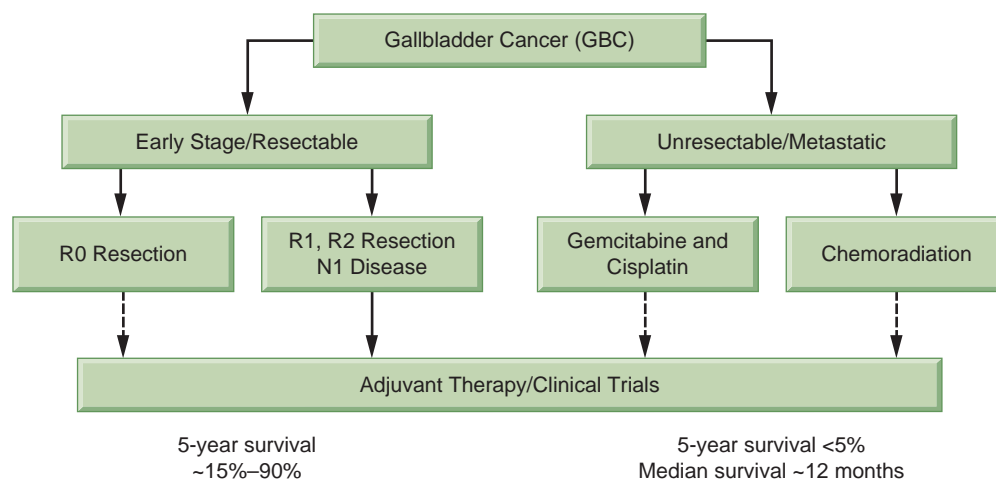

Figure 53.4 Algorithm for the management of gallbladder carcinoma.

be curative. Direct tumor growth into the liver or duodenum or colon is not a contraindication to surgery, but the extent of spread will guide the extent of resection for these T2 to T4 lesions. Thus, wedge resection of the liver, portal lymph node dissection, and extrahepatic bile duct resection, or even a pancreaticoduodenectomy may be needed in addition to a cholecystectomy. If there is obvious penetration to the serosal layer on the deep surface of the gallbladder, or if margins are positive, or the muscularis has been penetrated, resection of at least liver segments IVb and V, and a lymph node dissection are performed. If the cystic duct resection margin is positive, then, in addition, the extrahepatic bile duct is excised to clear margins. A more extensive liver resection may be required if the tumor has penetrated further into the liver. If negative resection margins are achieved, 5-year survival rates range from 90% in stage I disease, 80% in stage II, 40% in stage III, and 15% in stage IV. Lymph node involvement portends a worse prognosis than local hepatic invasion alone.^{243,245} A pancreaticoduodenectomy may be considered for T2 to T4 disease, but the results remain poor in advanced stages.²⁴⁶

Randomized studies did not show a benefit of preoperative biliary decompression for jaundiced patients.²⁴⁷⁻²⁴⁹ However, these studies were performed in an era in which surgical intervention mostly involved palliative bypass of the biliary tree, and the potential benefits of preoperative decompression prior to either pancreaticoduodenectomy or liver resection are not defined.

Adjuvant Therapy. GBC has a high risk of systemic spread and local–regional failure and adjuvant chemotherapy and radiotherapy are recommended by most cancer centers.

As with other biliary tract cancers, published reports on adjuvant radiotherapy or chemoradiation therapy after a resection for gallbladder cancer consist of retrospective reviews that vary in the type of radiation treatment (e.g., EBRT, brachytherapy, or IORT) and the extent of surgical resection (complete or incomplete). As a result, they cannot provide adequate evidence upon which a standard treatment recommendation could be based.

A median survival of approximately 2 years has been reported for patients receiving adjuvant therapy.

In a study of 21 patients who received postoperative adjunct EBRT with 5-FU, EBRT was applied to a median dose of 54 Gy in fractions of 1.8 to 2.0 Gy per day, with one patient also receiving 15 Gy of IORT after EBRT, the median survival rates were 0.6, 1.4, and 15.1 years, and 2-year local control rates were 0%, 80%, and 88% for patients with gross residual tumor, microscopic residual tumor, and no residual disease, respectively.²⁵⁰ For six patients who received more than 54 Gy, the 3-year local control rate was 100% compared with 65% for 15 patients who received less than 54 Gy. In a randomized trial comparing mitomycin C and 5-FU with observation alone that enrolled 140 patients with gallbladder cancers, a significantly better 5-year survival was seen with chemotherapy, but these differences were not apparent when an intent-to-treat analysis was performed.¹⁴¹

Chemotherapy. Although the role of chemotherapy given in the adjuvant setting has not been defined definitively, given the poor outcomes for patients with resected disease, it remains an area of active investigation. As described earlier, data from pivotal phase III studies using gemcitabine- or fluoropyrimidine-based

regimens is eagerly awaited. New approaches beyond the currently available chemotherapeutic agents are needed for these cancers to achieve any improvements in survival. Understanding the molecular and genomic contributors to this cancer may enable more focused therapy in the future.

Palliative Care. Advanced GBC has a 1-year survival rate of less than 5%. Although the resection of gross disease may provide palliation and, in some instances, a chance for cure, it may not always be possible. Patients with advanced disease should be considered for clinical trials. The aggressive nature and dismal prognosis of advanced unresectable cancer should be considered when deciding on palliative management. The goals of palliative treatment are to prevent biliary and bowel obstruction and to relieve pain.

Stenting. If biliary obstruction is present, percutaneous stenting for relief of obstruction can be performed by percutaneous or endoscopic approaches similar to that for other cancers such as dCCAs and pCCAs.

Surgery. Surgical bypass is not usually warranted because of the poor expected survival. The resection of hematogenous metastasis or of distant nodal disease is not justified.

Chemotherapy. In the UK-ABC-02 study described earlier, 36.3% (149 of 410) of the patients had advanced gallbladder cancer. The response rate was 37.7% versus 21.4%. Median overall survival and progression-free survival differences were not reported separately, but the survival benefit did demonstrate significance on a subgroup analysis in patients with gallbladder cancer (HR, 0.63; 95% CI, 0.42 to 0.89). As such, the standard of care in patients with advanced GBC is also regarded to be gemcitabine in combination with cisplatin. As described previously, although fluoropyrimidine-based therapies have shown evidence of preliminary efficacy, the role of subsequent lines of systemic chemotherapy remains to be definitively defined. Akin to CCA, therapeutic strategies based on genomic profiling of tumors will also be an area of critical study to best define approaches that can be more individualized in nature.

Regional Therapy. Regional therapy is possible for gallbladder cancer. In one study, a 48% overall response rate and a prolongation of median survival from 5 to 14 months compared with historical controls was reported with intra-arterial mitomycin C.²⁵¹

Radiation Therapy. EBRT may be considered for symptomatic patients. The limited data available suggest that tumor control is rarely possible, although some GBCs may be radiosensitive and spread is mainly by local–regional growth.^{252,253} However, radiation therapy may be considered for palliation of jaundice in some cases, or used in multimodality approaches combining EBRT with a 5FU-based treatment. The latter approach is supported by consensus guidelines from the European Society of Medical Oncology and the National Comprehensive Cancer Network.²⁵⁴ Although the benefit of EBRT is minimal, with a median survival of only 6 to 8 months, it does appear to be well tolerated and may improve symptoms and prolong survival in selected patients.

54 Cancer of the Small Bowel

Ronald S. Chamberlain, Krishnaraj Mahendraraj, and Syed Ammer Shah

SMALL BOWEL CANCER

Although the small intestine comprises 75% of the length and 90% of the total absorptive surface of the gastrointestinal tract, less than 3% of gastrointestinal malignancies occur in the small bowel.¹ Small bowel cancers (SBC) are 40- to 60-times less common than colorectal cancer. The rarity of SBCs makes them difficult to diagnose, especially considering their varied clinical presentation. With an increasing incidence and advanced stage at diagnosis, it has become even more important to understand the pathology of these rare but deadly cancers.

Epidemiology

SBC accounts for ~3% of all the gastrointestinal cancers with an equal male to female ratio and a median age of 66 years. The American Cancer Society estimates there will be 9,160 new cases of SBCs in 2014, with 1,210 deaths.^{2,3} This number represents a steady increase in the incidence of SBCs from ~6,100 new cases per year in the 1980s based on information derived from the Surveillance, Epidemiology, and End Results (SEER) database registries.^{1-5,8}

There are more than 40 SBC histologic subtypes, with 93% of them comprised of four major types: carcinoid (37.4%), adenocarcinoma (36.9%), lymphoma (17.3%), and gastrointestinal stromal tumors (8.4%).⁶ Historically, adenocarcinoma had a higher incidence than carcinoid tumors, but this has changed over the past decade.⁵⁻⁸ In terms of the location, ~50% of SBC occur in the duodenum, where adenocarcinoma predominates, followed by the jejunum (30%) and ileum, where lymphoma is more common proximally, and carcinoid tumors distally. There is an increased incidence of SBC among colon cancer patients and the reverse is true also, suggesting a similar causal mechanism rather than a surveillance bias or the carcinogenic effects treating the index primary.^{6,9,10}

Pathogenesis and Risk Factors

Proposed risk factors for the predisposition to small bowel neoplasms are varied, although it is notable that 64% of small bowel tumors are malignant. Proposed factors that have been associated with SBC include:

1. Advanced age: SBCs occur predominantly in the elderly with a mean age of ~66 years.
2. Specific inheritable syndromes predisposing to SBC¹¹⁻³²:
 - **Familial adenomatous polyposis (FAP) syndromes.** FAP is an autosomal-dominant disorder attributable to a mutation in the adenomatous polyposis coli (APC) gene and characterized by the development of hundreds or thousands of polyps throughout the gastrointestinal tract, but predominantly in the large bowel. FAP patients have a 100% lifetime risk of developing colorectal cancer, and this has led

to a clearly defined role for total colectomy or proctocolectomy to prevent cancer development. FAP patients also inherit a 4% to 12% lifetime risk of developing adenocarcinoma of the duodenum or periampullary region, which is 300 times that of the general population, necessitating screening esophagogastroduodenoscopy (EGD) as part of the work-up.¹¹⁻¹⁸

- **Hereditary nonpolyposis colon cancer (HNPCC).** HNPCC, also known as Lynch syndrome, is a hereditary condition that results from a germ-line mutation in DNA mismatch repair genes, primarily *MSH2* and *MLH1*. This mutation predisposes one not only to an 80% lifetime risk of colorectal cancer, but also to an increased risk of endometrial, gastric, ovarian, urinary, small bowel, biliary, and skin cancers.^{19,20} HNPCC patients have a SBC lifetime risk of 1% to 4%, or a 100-fold greater risk than the general population, which also tends to present 10 to 20 years earlier.²⁰ SBC may be the initial presentation of HNPCC in a small cohort of patients, and some clinicians recommend small bowel surveillance for this group.²⁰⁻²⁵
 - **Peutz-Jeghers syndrome (PJS).** PJS is an autosomal-dominant disorder characterized by benign hamartomatous polyps in the intestine along with melanocytic macules on the lips and oral mucosa. PJS is due to a mutation in the *STK11 (LKB1)* tumor suppressor gene, which results in a significant increased inherited risk for multiple cancer types, with the highest risk involving the gastrointestinal tract. By the age of 70 years, the cumulative gastrointestinal (GI) cancer risk is approximately 57% (colon cancer followed by SBC), which represents a 15-fold increased risk compared to the general population.^{27,28}
 - **MUTYH-associated polyposis (MAP).** First described in 2002, the *MUTYH* gene encodes for DNA glycosylase, which is involved in oxidative DNA damage repair and belongs to the family of DNA mismatch repair genes. Mutations in this gene result in heritable predisposition to GI cancers, including SBC in an autosomal-recessive fashion. Mutations of this gene results in G to T transversions, usually involving the *APC* and *KRAS* gene, thus predisposing individuals to cancer development.^{29,30}
 - **Cystic fibrosis.** A marginally increased risk of SBC has been documented in cystic fibrosis patients.³¹
3. **Inflammatory bowel disease.** Although only 2% of Crohn disease (CD) patients will develop a small bowel malignancy (typically an adenocarcinoma associated with >10 years of disease and involving the distal small bowel), this represents a 10- to 60-times higher risk than the general population.³³⁻³⁵ Specifically, SBCs in CD occur more commonly in men, in the distal ileal location, are more common in small bowel bypass loops and in strictures, and in patients with exposure to asbestos or other carcinogens such as halogenated aromatic compounds.³⁶ A meta-analysis identified a 33.2 relative risk (95% confidence interval [CI], 15.9 to 60.9) of developing small bowel cancer among CD patients.³⁷⁻³⁹

4. **Celiac disease or sprue (CS).** CS is an autoimmune disorder characterized by villous atrophy, crypt hyperplasia, and increased intraepithelial lymphocytes caused by a reaction to the wheat protein gliadin in the presence of specific pairs of allelic variants in two HLA *DQ2/DQ8* genes. CS is associated with an increased risk of *enteropathy-associated T-cell lymphoma* (EATL), which can occur in up to 39% of patients with severe or refractory CS (RCS). The overall prevalence of RCS is low (0.6% to 1.5%). RCS can be subclassified into RCS type 1, which is characterized by increased but nonclonal expansion of intraepithelial lymphocytes (IEL), or RCS type 2, which displays clonal expansion of IELs that evolve into EATL in 60% to 80% of such patients within 5 years.^{40–42}
5. **Immunosuppression.** Iatrogenic (therapeutic) or posttransplant immunosuppression is a generalized dysregulator of homeostasis and predisposes certain patients to both lymphomas and sarcomas. Small bowel lymphomas that develop in these patients are predominantly B-cell as opposed to T-cell lymphomas. Posttransplant lymphoproliferative disorders (PTLD) that occur develop primarily post–Epstein Barr viral infection and are typically B-cell lymphomas.
6. **Other malignancies.** The patient with other primary malignancies may also be at increased risk for SBCs. This includes patients with prior colorectal, pancreas, periampullary, uterine, ovarian, prostate, thyroid, skin, and soft tissue tumors.^{9,10,43} In fact, 30% to 40% of patients with SBCs have a synchronous malignancy, which may be associated with the primary pathologic entity or may reflect shared genetic or environmental risk factors.
7. **Modifiable risk factors.** Modifiable risk factors implicated in SBCs include alcohol use and obesity. In a recent large Asian study involving over 500,000 patients with a 10.6-year follow-up, a higher body mass index (>27.5 kg/m²) and alcohol use (>400 g of ethanol per week) were associated with increased SBC risk. Notably, smoking is not associated with an increased risk of developing SBC.^{44–46} Abstinence, weight loss, and dietary modifications (including adhering to a gluten-free diet in those with celiac disease) have been suggested to reduce the risk of SBCs.

Clinical Features

SBC presents in a variety of ways and is more likely to be symptomatic early in the disease course compared to benign tumors.^{47,48} The most common presenting symptoms are abdominal pain (45% to 76%), nausea and vomiting (16% to 52%), weight loss (28% to 45%), fatigue and anemia (15% to 30%), and gastrointestinal bleeding (7% to 23%).^{49–52} The most common clinical sign

of pallor is seen in ~40% of patients. Up to 77% of SBCs present acutely with either small bowel obstruction or perforation, particularly adenocarcinomas.⁴⁷ Patients with familial or genetic predisposition to SBCs present, on average, 10 years earlier compared to sporadic cases.^{52–56}

In comparing different SBC histologies, adenocarcinoma is most often associated with abdominal pain and obstruction, whereas sarcomas and lymphomas are more often associated with bleeding and perforation, respectively. Adenocarcinomas are frequently found in the duodenum, carcinoid tumors affect the ileum and sarcomas, and lymphomas are found throughout the entire small bowel.

Diagnosis

The diagnosis of SBC is often delayed as a result of its rarity and nonspecific presentation. The mean duration of symptoms prior to an accurate SBC diagnosis ranges from 8 to 12 months.^{48–51} A high index of clinical suspicion is imperative if the diagnosis is to be made early. In many instances, a preoperative diagnosis is not established because patients present emergently with hemorrhage, perforation, or obstruction. No single diagnostic test has sufficient sensitivity or specificity to be considered a gold standard.^{141–167}

Conventional abdominal radiographs have a limited, nonspecific role in the diagnosis of SBCs. Plain abdominal radiographs are helpful when an obstruction exists, but even then accuracy is only 50% to 60%. A single or double contrast small bowel follow through (SBFT) is well suited for examination of luminal abnormalities and mucosal abnormalities, but is time consuming and associated with an accuracy ranging from 33% to 60%.^{78–82} Small bowel enteroclysis may improve this accuracy to 90%.⁵⁷ A major limitation of both SBFT and enteroclysis is their inability to evaluate extraluminal pathology, which is circumvented by cross-sectional imaging, such as computed tomography (CT) scans and magnetic resonance imaging (MRI). CT- and MRI-based enteroclysis has improved the sensitivity and specificity of small bowel tumor detection compared to conventional enteroclysis.^{58–60}

In clinical practice, a CT scan of the abdomen with oral and intravenous contrast is the most common diagnostic test utilized in the acute and chronic setting. Pathognomonic CT signs that differentiate between types of small bowel lesions have been well described. Adenocarcinoma appears as a discrete tumor mass with annular narrowing, abrupt concentric or irregular “overhanging edges,” or as an ulcerative lesion. Lesions in the duodenum are typically intraluminal polyps, whereas more distal polypoid lesions present with intussusception and a characteristic “target sign” (Figs. 54.1 and 54.2).⁶¹

Figure 54.1 Moderately differentiated primary small bowel adenocarcinoma. **(A)** The contrast-enhanced axial computed tomography image shows an annular soft tissue lesion (arrows) in the duodenum, resulting in circumferential luminal narrowing and wall thickening. **(B)** A lateral image from subsequent upper gastrointestinal series shows the annular “apple-core” lesion, resulting in advanced narrowing of the duodenal lumen (arrows). Note the compressed, overhanging edges (arrowhead) of the small bowel at the margin of the mass.

Figure 54.2 A small bowel intussusception due to primary small bowel adenocarcinoma. **(A)** A contrast-enhanced axial computed tomography image shows a small bowel target sign consistent with intussusception; the intussusceptum (*arrowhead*) telescopes into the intussuscipiens (*arrow*). The lead point for the intussusceptions was a primary small bowel carcinoma. **(B)** An image from small bowel follow through shows the “coiled spring” appearance of the intussusceptum (*arrowhead*) as it telescopes into the intussuscipiens (*arrow*).

Carcinoid tumors appear as hyperintense luminal masses due to increased vascularity. The tumors typically have intense desmoplastic reaction in response to biochemical products produced by the tumor that results in puckering of the adjacent mesentery, giving a characteristic stellate pattern on the CT scan not necessarily reflecting mesenteric invasion (Fig. 54.3).

Small bowel lymphomas present as circumferential mural thickening with low homogeneous attenuation and a characteristic aneurysmal dilatation in which the involved segment shows cavitory dilatation with a nodular, irregular luminal contour and peripheral bowel wall thickening (Fig. 54.4).⁶² Sarcomas appear as homogeneous, well-circumscribed, hypervascular masses on CT (Fig. 54.5).^{63–65}

The MRI has a defined niche in the assessment of early small bowel lesions given its improved soft tissue delineation and it may be pivotal in detecting early small bowel pathology (Table 54.1).^{66–70} Somatostatin receptor scans (octreoscan) and metaiodobenzylguanidine (MIBG) scans may be helpful in localizing and diagnosing of small bowel carcinoid tumors. Octreoscan employs a ¹¹¹In-diethylenetriaminepentaacetic acid analog that targets somatostatin receptors. Over 90% of carcinoid tumors express somatostatin receptors, and this test has a sensitivity of 80% to 100%. Octreoscans may also provide a functional map of the tumor for anticipated radiolabelled immunotherapy-targeted therapy depending on the stage of the disease.⁷¹

Positron emission tomography (PET)/CT scans are useful in the initial diagnosis and in disease staging for small bowel adenocarcinomas (SBA), lymphomas, and gastrointestinal stromal tumor

(GIST).^{72,74} Fludeoxyglucose (¹⁸FDG)-PET has a limited role in the diagnosis and staging of carcinoid tumors because they are not ¹⁸FDG avid; however, it may play important role in ascertaining treatment response and detecting disease recurrence.^{72–74}

Two notable advances are double-balloon enteroscopy, or push enteroscopy, and video capsule endoscopy (VCE), which were both introduced in 2001. Double-balloon enteroscopy is a technically challenging procedure that permits the evaluation of the entire small bowel and tissue sampling, which is not possible with VCE. Double-balloon enteroscopy most commonly detects symptomatic lesions, including areas of ulceration, stenosis, and GI bleeds, with a sensitivity of 74% to 81%.^{75–83} VCE is effective at identifying 50% of new SBC lesions and 87% of all lesions, with a relatively low miss rate of 10%.^{84–93}

ADENOCARCINOMA

Adenocarcinoma of the small bowel is the second most common histologic SBC subtype, comprising 36.9% of cases.⁹⁴ The annual incidence is estimated at 7.3 case per million worldwide. In the United States, 3,050 new cases of SBA are anticipated in 2013.^{94,95} Patients with SBA usually present between the 6th and 8th decade of life, with earlier presentations in patients with genetic, autoimmune, or inflammatory conditions (Table 54.2).

SBAs display a slight predominance for men, with age-adjusted incidence rates highest among African Americans (14.1 per 10⁶) followed by Caucasians (7.7 per 10⁶), Hispanics (6.2 per 10⁶), and

Figure 54.3 Primary ileal carcinoid. **(A)** A contrast-enhanced computed tomography (CT) shows a tethered and thickened segment of ileum (*asterisk*) containing a small submucosal enhancing lesion (*arrow*), consistent with primary carcinoid. Note partially imaged metastasis (*arrowhead*) in the adjacent mesentery. **(B)** A more inferior CT image shows a stellate mesenteric carcinoid metastasis (*arrows*) with central calcification and desmoplastic reaction (*arrowheads*) in the adjacent fat.

Figure 54.4 Primary small bowel lymphoma. **(A)** A contrast-enhanced computed tomography (CT) image shows aneurysmal luminal dilatation and extensive wall thickening of a segment of small bowel (arrows). Note enlarged adjacent mesenteric node (arrowhead). **(B)** A radiograph from the small bowel follow through shows a small bowel segment with luminal dilatation (arrow) and extensive mural thickening and irregularity (arrowheads) corresponding to the diseased segment on the CT.

Asian/Pacific Islanders (5.5 per 10⁶). Adenocarcinoma incidence decreases distally in the small bowel, with the highest incidence in the duodenum (50% to 5%), followed by the jejunum (16%) and ileum (13%). Most SBA patients present at an advanced stage (American Joint Committee on Cancer [AJCC] stage III or greater) resulting in a poor overall 5-year disease-free survival (of about 30%) and mean survival (20 months).⁵⁰ Outcomes are worse for duodenal tumors (28% 5-year survival) compared to jejunal and ileal lesions (38% 5-year survival).

Etiology

SBA shares several etiologic features with colorectal cancers (CRC), leading to the adoption of similar treatment strategies, although they are biologically distinct diseases. The most obvious similarity between SBA and CRC is a common etiopathogenic pathways because both cancers are more common in patients with FAP, HNPCC, and inflammatory bowel disease. Available data imply a similar adenoma to carcinoma sequence in both SBA and CRC. As with CRC, the risk of progression is associated with the size of the adenoma (8.3% for lesions <1 cm and 30% for lesions >1 cm) and histology (14.3% for tubular, 23.1% for tubulovillous, and 36% for villous).⁹⁶⁻⁹⁹ A number of molecular similarities and dissimilarities between these two cancers have also been reported. In a recent genomic hybridization study looking at GI cancers, SBA was more similar to CRC than to stomach cancer.¹⁰⁰ In addition, *HER2* oncogene amplification is low in SBA similar to CRC in contrast to gastric cancer.^{97,98,101,102} Microsatellite instability (MSI) and loss of mismatch repair proteins is present in 18% to

35% of SBAs versus 15% of CRCs.⁷⁷⁻⁷⁹ Approximately 50% of the SBA cases reflect sporadic methylation of the *MLH1* gene with a relatively high incidence of MSI and *MLH1* methylation in CD associated SBA (67% to 73%).¹⁰⁶⁻¹¹⁷

Staging and Prognosis

The AJCC staging system for SBA is depicted in Table 54.3. Given the nonspecific initial presentation of SBAs, 32% of patients present with stage IV disease, 27% present with stage III, 30% present with stage II, and 10% present with stage I.¹⁰² Less than 50% of SBA patients are curative surgical candidates. Survival by stage is 63% for stage I, 48% for stage II, 32% for stage III, and about 4% for stage IV.¹⁰² Multivariate regression analyses identified age over 55 years, males, African Americans, T4 tumor, lymph node involvement and ratio, duodenal followed by ileal primary, poor differentiation, metastatic disease, and positive margins as associated with a poor prognosis.^{94,102,120-122} Recent investigations into molecular determinants have also identified the CpG island methylator phenotype (CIMP) status, E-cadherin loss, and aberrant β -catenin expression as also associated with a worse prognosis.^{106,118}

Management

The site of the disease, the stage at presentation, the available expertise, patient comorbidities, and patient performance status are all important considerations in determining the optimal management for individual SBA patients.

Figure 54.5 A gastrointestinal stromal tumor of the small bowel. **(A)** A contrast-enhanced computed tomography image shows a solid, heterogeneously enhancing mass (arrows) arising from the submucosa of the third portion of the duodenum. **(B)** An image from upper gastrointestinal series shows a filling defect (arrow) in the third portion of the duodenum due to the submucosal gastrointestinal stromal tumor.

TABLE 54.1

Risk Factors and Predisposing Conditions in the Development of Small Bowel Cancer

Risk Factor	Lifetime Risk	Small Bowel Cancer Type
<i>Genetic</i>		
FAP (2%–5%) HNPCC Peutz-Jeghers syndrome MUTYH-associated polyposis Cystic fibrosis	2%–5% 1%–4% 15-fold 4%	Periampullary adenocarcinoma, duodenal/jejunal adenocarcinoma, adenocarcinoma, Gardner syndrome, desmoid duodenal adenocarcinoma, gastrointestinal cancers
<i>Autoimmune/Inflammatory</i>		
Crohn disease	(>10 yr) 2%	Ileal adenocarcinoma, jejunal lymphoma/ adenocarcinoma, celiac disease immunosuppressive lymphoma, posttransplant lymphoproliferative disorder, neurofibromatosis, paragangliomas
Malignant Conditions Colorectal, prostate, pancreas, uterine, skin and soft tissue tumors		
Benign Conditions Cholecystectomy, peptic ulcer disease		
Other Conditions Male gender, African American, advanced age, high-fat diet, obesity, alcohol		

TABLE 54.2

Magnetic Resonance Findings of Common Small Bowel Neoplasms

Tumor Type	Growth Pattern	Margins	Secondary Intestinal Findings	Type of Lymphatic and Mesenteric Spread	MRI Findings
Adenocarcinoma	Short annular lesion with intraluminal growth, predominantly in duodenum	Irregular margins	Stenotic lesion with proximal obstruction	Local–regional metastases	Isointense to muscle on T1, heterogeneous signal on T2, hypovascular after Gd
Lymphoma	Long segmental infiltrating lesion	Smooth regular contours with preservation of the perivisceral fat plane	Aneurysmal dilatation without obstruction	Bulky retroperitoneal metastases	Isointense to muscle on T1, heterogeneous signal on T2, moderate enhancement after Gd
GIST	Intramural submucosal mass with extraserosal extension	Smooth lobulated contours	Aneurysmal dilatation, stenosis or obstruction usually absent	Peritoneal metastatic nodules, adenopathy rare	Inhomogeneous lesions, isointense on T1, mildly hyperintense on T2, peripheral enhancement in large lesions
Carcinoid	Focal asymmetric predominantly in ileum	Irregular margins; mesenteric stranding and kinking of the involved segment	Intermittent obstruction possible proximal to the kinked loop	Hypervascular mesenteric metastases with spiculated margins and local adenopathy with calcification	Isointense to muscle on T1, heterogeneous hyperintense on T2, hypervascular on Gd

Gd, gadolinium.

Surgery for Local–Regional Disease

Surgery is the treatment for local–regional confined SBAs.⁵⁰ The 5-year survival of resected versus unresected patients is 54% versus 0%.¹²² The optimal surgical treatment depends on the location of the primary tumor, with duodenal adenocarcinomas managed by either a pancreaticoduodenectomy or segmental resection. Both procedures are equivalent with regard to long-term survival, with segmental resection associated with less postoperative morbidity and length of hospitalization.^{122–125} Jejunal and ileal adenocarcinomas

are treated with oncologic-appropriate segmental resection. A right hemicolectomy is the appropriate oncologic approach to tumors near the ileocecal valve.

Adjuvant Therapy

Recurrence in SBAs is predominantly distant and rarely local–regional (86% versus 18%, respectively).⁵⁰ Although duodenal SBAs have a higher incidence of local failure, distant recurrence still predominates (59% versus 19%, respectively, and combined, 22%).^{94,126,127} Most treatment strategies are based on fluorouracil (5-FU) or, more recently, 5-FU/oxaliplatin–based regimens. Overman et al.¹²⁹ reported adjuvant therapy improved disease-free survival (hazard ration [HR], 0.23, 95% CI, 0.06 to 0.89, $p = 0.03$), but not overall survival (HR, 0.48, 95% CI, 0.13 to 1.74, $p = 0.26$) in patients receiving adjuvant chemotherapy (5-FU or platinum based).¹²⁹ Multiple retrospective studies have demonstrated a mixed response for adjuvant chemotherapy in SBAs.^{49,50,128–130}

The role of hyperthermic intraperitoneal chemotherapy (HIPEC) in the treatment of SBCs has been investigated in four small trials involving a total of 30 patients with peritoneal carcinomatosis. These patients underwent HIPEC followed by adjuvant chemotherapy, with a reported mean overall survival of 22.2 months compared to 12 months on conventional treatment strategies. The results are encouraging, but the numbers are too small to draw any robust conclusions.¹⁴⁰

Treatment for Metastatic Disease

Limited randomized controlled trials defining a role for chemotherapy versus best supportive care (BSC) in patients with advanced SBAs have been performed. Multiple retrospective studies have demonstrated a small survival advantage for palliative chemotherapy approaches compared to BSC alone (Table 54.4).^{49,50,131–136}

Although there are no randomized trials comparing different regimens, a number of SBA clinical trials are currently accruing in an effort to more precisely define the role of chemotherapy in advanced SBA. The role of surgery for all advanced/metastatic SBC is purely palliative. Specific patients might benefit from an intestinal bypass to maintain an enteral means of nutrition and an improved quality of life.^{120,137–139}

CARCINOID TUMORS

Carcinoid tumors are slow growing neoplasms that arise from the neuroendocrine cells of Kulchitsky. Of these cells, 75% occur in the gastrointestinal tract (44.7% in the small bowel and 19.6% in the rectum), followed by the lung, bronchus, and rarely the liver, pancreas, or gonads. Given the fourfold increase in the incidence of carcinoids that has occurred over the past 2 decades, carcinoids are now the most common SBC (36.9%) according to the National Cancer Database.^{167,168}

Clinical Presentation and Prognosis

Of small bowel carcinoids, 44.7% occur in the small bowel, and over 50% of these are found in the ileum.¹⁶⁸ Carcinoid tumors are most common in the 7th decade of life (mean age, 66 years), in males (52.4%), and in Caucasians (80.4%). Most carcinoids present in an advanced stage (75%) as a result of a significant delay and difficulty in diagnosis. Despite the advanced stage, most carcinoids follow an indolent course, with an overall 5-year survival ranging from 52% to 77%.^{170–174} Tumors over 10 mm and those with a transmural depth of invasion are the primary risk factors for local–regional progression and metastasis.¹⁷⁵

Carcinoid Syndrome

Carcinoid syndrome is an array of symptoms that occurs in patients with carcinoid tumors of the bronchus or metastatic to the liver. Symptoms of carcinoid syndrome include diarrhea, cutaneous flushing, and wheezing. These symptoms are precipitated by stress, alcohol intake, and certain physical activities, and are secondary to the systemic release of several tumor-derived factors, including serotonin, dopamine, tachykinins, histamine, and prostaglandins, all of which are metabolized by the liver. Up to 80% of patients with small bowel carcinoids develop carcinoid syndrome, and it is the presenting complaint in 10% to 17% of patients. The mainstay of treatment for carcinoid syndrome is somatostatin, which prevents the secretion of hormones by binding to a specific receptor on the tumor surface.^{192,193} Although octreotide is effective in most patients, interferon α (IFN- α) may benefit patients who do not respond to octreotide alone.¹⁸⁷ The antihistamine cyproheptadine has also been used successfully for refractory carcinoid symptoms.¹⁸⁸

Management

Surgery for Local–Regional Disease

An oncologic segmental resection of the tumor is the preferred treatment for localized small bowel carcinoids.¹⁷⁶ Five-year survival after resection of localized disease ranges between 50% and 85%. Of small bowel carcinoids, 29% are associated with other noncarcinoid neoplasms, necessitating a thorough inspection of the entire bowel at surgery. Appendiceal carcinoids smaller than 2 cm can be treated with a simple appendectomy, whereas larger tumors require a right hemicolectomy. Pretreatment with octreotide prior to anesthetic induction is recommended because surgical intervention/manipulation can precipitate a carcinoid crisis.^{177–180}

Surgery for Metastatic Disease

The liver is the most common site of carcinoid metastasis. Liver resection along with primary tumor resection is recommended for resectable metastatic disease. More radical surgical debulking or cytoreductive surgery has been used for patients with extensive bilobar liver disease, liver failure, or extensive metastatic disease to provide prolonged disease-free survival. Several studies have shown that liver resection can improve the 5-year survival rate from 36% to 61% compared to historic controls.^{181–183} Although long-term data are lacking, percutaneous or laparoscopic local ablative techniques such as radiofrequency, microwave, or cryoablation represent alternative cytoreductive modalities for the treatment of metastatic carcinoid tumors. Cytoreductive strategies not only prolong survival, but are also associated with a decrease in octreotide doses required to control carcinoid symptoms. A number of

retrospective series have demonstrated that surgical resection is superior to systemic therapy with regard to both overall survival and symptom management.¹⁸⁴

Hepatic Artery Embolization

Transcatheter hepatic arterial embolization (HAE) with or without chemotherapy has been utilized extensively for both symptom control and as a definitive treatment for unresectable carcinoid liver metastasis.¹⁸⁵ HAE may be performed with gel foam, polyvinyl alcohol, or microspheres. The addition of chemotherapy allows for the delivery of much higher intratumoral concentrations than can be achieved with systemic therapy. Known complications include transient or fulminant liver failure, liver abscesses, and postembolization syndrome (fever, abdominal pain, leukocytosis, elevations in liver function tests).¹⁸⁵

Systemic Chemotherapy

Several chemotherapeutics have been studied extensively in the management of carcinoid metastases, including 5-FU, streptozotocin, and doxorubicin. All have yielded modest response rates of ~20%. In addition, IFN- α has been purported to achieve tumor stabilization in 20% to 40% of cases, and octreotide has been shown to prevent the progression of metastatic carcinoids in several small case series.^{186–190} Tyrosine-kinase inhibitors like imatinib or sunitinib can induce a delay in tumor cell growth in preclinical studies and disease stability in 83% of patients treated over a 1-year period. In a recent phase II study, bevacizumab, a monoclonal antibody that targets vascular endothelial growth factor (VEGF), was shown to stabilize disease in 95% of patients when combined with octreotide compared to 68% stabilization when octreotide was combined with IFN- α .^{191,218,219}

Palliative Surgery

The decision to perform palliative resection for disseminated carcinoid tumors should carefully balance the surgical risks and perceived patient benefits. Orthotopic liver transplantation for patients with unresectable liver-only disease remains investigational and is currently performed by only a small number of transplant centers.

SMALL BOWEL LYMPHOMA

Lymphoma is the third most common SBC, comprising 10% to 20% of cases. Of such cases, 20% to 40% are extranodal lymphomas, which arise within a solid organ, and ~50% of extranodal lymphomas are GI lymphomas.^{194–198} Of GI lymphomas, 75% are located in the stomach, followed by the small bowel, colon, and other organs such as the pancreas and the liver. GI lymphomas

have a peak incidence in the 7th decade of life, with a male to female ratio of 1.5:1. The incidence of small bowel lymphomas has increased in the United States over the last 2 decades, correlating with an increase in lymphomas among immunocompromised patients. Increased immigration from the Middle East—where primary intestinal lymphoma constitutes the most common primary extranodal disease—may also account for some of the increase in small bowel lymphomas. Additional risk factors include Crohn disease and prior radiation exposure.

Staging and Prognosis

The most important prognostic indicator for intestinal lymphoma is tumor spread. Most GI lymphomas are of the non-Hodgkin type and are staged based on the Ann Arbor staging system: stage I disease is limited to a single site; stage II tumors are confined to below the diaphragm and are separated into two subgroups, namely those with regional (stage II 1E) and distant (stage II 2E) lymph node involvement; stage III has involvement of organs on both sides of the diaphragm; and stage IV represents widespread dissemination, including the liver and the spleen. Primary intestinal lymphomas can be differentiated from secondary lymphomas by the absence of superficial and mediastinal lymphadenopathies on work-up, if there is no evidence of disease on both peripheral blood smears and bone marrow biopsies, if the disease is localized to a specific small bowel segment and regional draining mesenteric lymph nodes only, and if there is no evidence of hepatic or splenic involvement (except via direct extension from the primary tumor).

Variants

Mucosal-Associated Lymphoid Tissue Lymphoma

Marginal zone B-cell lymphomas (MALT) are the most common primary gastrointestinal lymphomas. They occur more commonly in the stomach, followed by the small bowel (most commonly, the ileocecal region), the colon, and the esophagus. MALTs occur predominately in men and peak in the 6th decade of life. They present as unifocal, ulcerated overhanging lesions, characterized by cellular heterogeneity and bearing close resemblance to normal gut-associated lymphoid tissue (Peyer patch and mesenteric nodal tissue). Nonneoplastic reactive lymphoid follicles surrounded by centrocytes are characteristic, with the neoplastic focus occupying the marginal zone or intrafollicular region. These tumor cells express elevated levels of immunoglobulin (Ig)M and B-cell-associated antigens (including CD19, CD20, CD22, and CD79a). Most tumors are CD5, CD10, and CD23 negative and CD43 variable. MALT lymphomas are not associated with *Bcl-2* or *Bcl-1* rearrangements.

MALT lymphomas may be associated with chronic inflammatory conditions, including autoimmune disorders such as Sjögren syndrome and Hashimoto thyroiditis. The majority of patients present with stage I or II disease. Therapy is multimodal and includes surgical resection and/or chemoradiation therapy, with small bowel lymphomas having a better prognosis than gastric tumors. Some studies suggest that MALT tumors may be antigen driven, especially by *Campylobacter jejuni* and *Helicobacter pylori*. Regression has been reported with eradication of *H. pylori* infection using antibiotics.¹⁹⁴

Diffuse Large B-Cell Lymphoma

The second most common small bowel lymphoma is diffuse large B-cell lymphoma (DLBCL), also known as large cell immunoblastic, large-cleaved follicular center cell, centroblastic D immunoblastic cell, or diffuse mixed lymphocytic and histiocytic cell. DLBCL occurs more frequently in men, with a median age of 54 to 61 years, and primarily involves the ileocecal region. DLBCLs present as unifocal ulcerated lesions, composed of diffuse large B cells with large nuclei that are twice the size of a normal lympho-

cyte. Tumor cells are CD19, CD20, CD22, and CD79a positive. *Bcl-2* gene mutation is present in approximately 30% of the cases. Immunosuppression is an important risk factor for DLBCL. Surgery is the mainstay of treatment for localized disease, followed by adjuvant radiation or chemotherapy.¹⁹⁵ Overall 5-year survival is between 50% and 70% with multimodality therapy.¹⁹⁶

Burkitt Lymphoma

Burkitt lymphoma of the small bowel accounts for <5% of all small bowel lymphomas. It can occur endemically or sporadically and is highly aggressive. The endemic subtype is seen predominantly in Central Africa; it affects children with a peak incidence at 8 years of age, is associated with Epstein-Barr virus (EBV) infection, and involves the GI tract in only 20% to 30% of cases. Conversely, sporadic Burkitt lymphoma occurs more commonly in Westernized countries, affects a broader age group, is not associated with EBV infections and commonly affects the GI tract (ileocecal region). Clinically, they can mimic appendicitis by presenting as large masses. Microscopically, cells are monomorphic medium-sized cells with round nuclei and an abundant basophilic cytoplasm. It is a rapidly growing tumor with short doubling time; the high rate of proliferation gives it a *starry sky* pattern due to the numerous macrophages that have ingested apoptotic tumor cells. Treatment primarily consists of chemotherapy, usually vincristine, cyclophosphamide, doxorubicin, and methotrexate.¹⁹⁷

Mantle Cell Lymphoma

Mantle cell lymphoma (MCL) is a rare primary GI lymphoma that follows either an indolent or very aggressive course. MCL commonly affects men (ratio, 4:1) in their 6th or 7th decades of life and has a predilection for the small bowel and colon. Macroscopically, MCLs appear as multiple, whitish polypoid lesions that share morphologic features with nodal lymphomas. CD5+ B cells are located within the mantle zone that surrounds the germinal centers. Four histologic subtypes have been described: nodular, diffuse, mantle zone, and blastic. The blastic type has the worst prognosis, whereas the nodular and diffuse types have the best prognosis. MCLs have been associated with t(11:14) (q13; q32) chromosomal translocation, causing overexpression of cyclin D1. The vast majority of MCLs present in stage IV disease.

T-Cell Lymphoma

T-cell lymphomas (TCL) of the small bowel are less common than their B-cell counterparts, accounting for approximately 15% of all small bowel lymphomas. TCLs affect men and women equally and most commonly arise in the jejunum or the proximal ileum. TCLs may remain localized; however, dissemination is common. They typically present as large circumferential ulcers, in the absence of large masses, with associated mesenteric lymphadenopathy. As with other types of lymphomas, obstruction and perforation are common presentations. Microscopically, transmural replacement of the intestinal wall by highly pleomorphic lymphoid cells may be seen. A large number of surrounding intraepithelial lymphocytes may also show cellular atypia. Tumor cells stain positive for CD3, CD7, CD8, and CD103 and negative for CD4. Small bowel TCLs are known as EATLs due to their association with long-standing enteropathies, primarily celiac disease. EATL is described in approximately 5% to 10% of all patients with celiac disease, and the relative risk of developing a lymphoma in this setting is 25- to 100-fold higher than normal patients. Prognosis is generally poor, with a 5-year survival rate of 10%.¹⁹⁸

GASTROINTESTINAL STROMAL TUMORS

GIST tumors arise from the intestinal cells of Cajal and are characterized by the presence of a gain-of-function c-kit (CD117) mutation. The c-kit protein codes for a tyrosine-kinase receptor involved in cellular proliferation, apoptosis, and differentiation.

Epidemiology and Genetics

GISTs are the most common mesenchymal tumor of the small bowel, despite comprising only 0.5% to 1% of all GI tumors. There are between 4,500 to 6,000 GISTs per year in the United States, with the stomach being the most common site.^{199–204} Incidence rates are equal in both genders and peak between 50 and 60 years of age. Small bowel GISTs are most commonly found in the jejunum, followed by the ileum, and the duodenum and typically present with pain, intussusception, or bleeding. Approximately 80% to 90% of all GIST tumors contain a c-kit mutation (CD117), whereas the remainder have a mutation in another tyrosine-kinase receptor gene or platelet-derived growth factor (PDGF) receptor alpha. It is now recognized that a vast majority of tumors previously identified as leiomyomas and leiomyosarcomas were actually CD117+ GIST. The molecular discoveries have allowed for the development of the specific c-kit tyrosine-kinase inhibitor imatinib (Gleevec), a drug initially designed to treat chronic myelogenous leukemia.

Prognosis and Behavior

All GISTs have the potential for malignancy, and approximately 50% of resected patients will have disease recurrence within 5 years. Of GISTs, 30% to 50% are clinically malignant. Most GISTs have a c-kit gain-of-function mutation, allowing for the prediction of clinical behavior and recurrence risk stratification.^{205–208} Tumors larger than 2 cm have a higher risk of recurrence and metastasis. This risk increases significantly for tumors larger than 3 cm to 5 cm. The mitotic rate has also been studied, and GISTs with five or more mitoses per 50 high-powered field (HPF) have a worse prognosis, whereas mitotic rates higher than 10 per 50 HPF predicts high recurrence and metastatic rates regardless of tumor size or location, with 5-year survival rates ~25%. The tumor site also plays an important role in prognosis, with jejunal and ileal GISTs displaying more malignant behavior compared to duodenal, rectal, or gastric GISTs.

Management

Surgery

R0 surgical resection is the mainstay therapy for all GISTs. Extensive resection of the surrounding uninvolved tissue has not been shown to improve outcomes. A routine lymphadenectomy is not indicated because GISTs rarely metastasize to regional lymph nodes. Intraoperative tumor rupture and spillage has been linked to carcinomatosis, necessitating a meticulous surgical technique. The peritoneum and liver are the main sites of metastasis and recurrence, and both should be inspected during surgical exploration.^{209–212}

Adjuvant Therapy

Adjuvant imatinib therapy improves recurrence-free survival after complete surgical resection of localized disease. The ACOSOG Z9001 trial was a randomized phase III double-blinded, placebo-controlled multicenter trial where 713 patients were assigned to receive either 400 mg of imatinib or placebo daily for 1 year after complete resection of a c-kit–positive, 3 cm (or more) GIST. One-year progression-free survival was 98% in the imatinib arm and 83% in the placebo arm.²¹³

Similar results were found in the Z9000 trial, a phase II, intergroup trial led by the American College of Surgeons Oncology Group, in which 106 patients who had undergone complete surgical resection of GIST were prescribed imatinib 400 mg per day for 1 year followed by serial radiologic evaluation. At 7.7 years of follow-up, the patients receiving imatinib had 1-, 3-, and 5-year overall survival rates of 99%, 97%, and 83%, respectively,

compared to a 5-year overall survival rate of 35% for historic controls. Progression-free survival for 1, 3, and 5 years was 96%, 60%, and 40%, respectively.²¹⁴

In patients in whom the initial complete surgical resection is not possible, the use of imatinib therapy has resulted in a significant prolongation of survival, with 80% of patients achieving a 5-year overall survival versus 9 months' survival with no therapy.²¹⁵ Neoadjuvant imatinib is also effective at reducing large tumor burdens and may facilitate margin-negative, organ-sparing resections.^{216,217} Regorafenib is another novel multitargeted kinase inhibitor being used in GIST management that inhibits the Ras/Raf/Mek pathways as well as VEGF receptor 2 (VEGFR2) signaling.²¹⁹

OTHER MESENCHYMAL TUMORS

Leiomyomas and Leiomyosarcomas

Small bowel leiomyomas and leiomyosarcomas arise from the muscularis propria and muscularis mucosa. They have a varied presentation, primarily involving tumor ulceration and bleeding as the tumor enlarges. Because tumor growth is initially localized and primarily extraluminal, obstruction does not occur until very late in the disease course.²²³ Leiomyosarcomas stain positive for desmin and actin and are negative for CD117 (c-kit and CD34). Metastasis is via hematologic routes and is mainly to the liver and peritoneum. About one third of patients have metastasis at the time of diagnosis, and prognosis is very poor.^{228–231}

Desmoid Tumors

Frequently confused with GISTs, these spindle cell tumors originate from musculoaponeurotic structures throughout the body and are histologically defined by fibroblastic proliferation and the formation of bundles of spindle cells around blood vessels in a dense hypocellular fibrous stroma. Desmoids occur with higher frequency in patients with FAP and Gardner syndrome.²³⁴ Few mitotic figures are seen, and necrosis is usually absent. Desmoids stain for vimentin, smooth muscle actin, and nuclear beta catenin. Although desmoid tumors are benign with no potential for metastasis, they tend to be locally aggressive and recur even after complete resection.²³⁸ Treatment is surgical resection with a wide margin to ensure negative microscopic margins; however, this may be difficult due to the anatomic location and the involvement of vital structures. Other treatment modalities include chemotherapy (methotrexate and vinblastine, doxorubicin), radiation therapy, nonsteroidal anti-inflammatory agents, and antiestrogens (tamoxifen).^{235–237}

Inflammatory Fibroid Polyps

These benign lesions are uncommonly seen in the small bowel. They are typically submucosal and consist of a mixture of small granulation tissue–like vessels, spindle cells, and inflammatory cells. They can stain positively for CD34; however, they do not stain for CD117 with the exception of very small areas of stroma within these tumors.^{232,233}

Schwannomas

Although relatively rare in the small bowel, schwannomas of the GI tract are often found in the stomach, colon, and esophagus. They are benign lesions, and present as rubbery yellowish trabeculated tumors characterized by lymph node aggregates around their periphery with nuclear palisading Verocay bodies and hyalinized vessels similar to schwannomas found elsewhere in the body. Schwannomas stain strongly for S100 and glial fibrillary acidic protein, but are CD117, CD 34, and smooth muscle actin negative.^{224,225}

Inflammatory and Myofibroblastic Tumors

Inflammatory mesenchymal tumors typically present as solid white masses with infiltrative margins. Although their precise etiology is uncertain, several authors have suggested that they are benign reactions to infectious processes, although local recurrence has been reported. These tumors rarely behave in a malignant fashion and are histologically composed of spindle cells admixed with lymphocytes and plasma cells. Unlike GIST, they stain negatively for CD117 and CD 34, but positive for desmin, muscle-specific actin, and cytokeratin.^{226,227}

METASTATIC CANCER TO THE SMALL BOWEL

Metastatic tumors to the small intestine are 2.5 times more common than are primary SBCs. Metastatic spread to the small intestine from distant primary sites is more frequent than to any other site in the GI tract. The main routes by which secondary neoplasms reach the small bowel is primary dependent and includes direct extension (for colonic, pancreatic, and gastric cancers), intraperitoneal spread (ovarian cancer), and lympho- or hematogenous embolization (melanoma, and lung and breast cancers).

Epidemiology

Melanoma is the most common cancer to metastasize to the small bowel, with up to 4.4% of all melanoma patients demonstrating small bowel metastases. Malignant melanoma is the primary tumor in 50% to 70% of all small bowel metastases, with the terminal ileum being the most often affected site.^{220–223} Primary

melanomas of the intestine are extremely rare, with few case reports found in the literature.²³⁹

Clinically, small bowel metastases can present with obstruction, perforation, intussusception, malabsorption, and/or GI bleeding. Obstruction is commonly seen in association with metastatic lobular breast carcinoma. A wide array of nonspecific symptoms may also be present, including abdominal discomfort, distension, and diarrhea. Typical features of intestinal metastases include intestinal wall thickening, submucosal spread, and ulcers. Melanomas and sarcomas may appear as nodules or polyps. Metastases are typically located deep within the submucosa or the muscularis propria of the small bowel, with little involvement of the mucosa.^{221–223}

Intestinal metastases usually represent at a late stage of the disease, during which other sites of hematogenous metastases are also frequently found. However, the prognosis for patients with small bowel metastasis varies widely according to the primary tumor type and patient-specific factors. Metastatic melanomas or renal carcinomas with isolated metastasis to the small bowel may be associated with prolonged survival after resection. Other more common primary tumors that metastasize to the small bowel are uterus, cervix, colon, lung, and breast tumors.

Management

The management of small bowel metastatic disease is defined by the primary tumor of origin. Isolated small bowel metastasis warrants segmental resection to prevent bowel obstruction, to maintain nutrition, or as part of a debulking procedure (e.g., ovarian, appendiceal). Most often, systemic therapy is the modality of choice for advanced/diffuse small bowel involvement. A diffuse disease may rarely warrant debulking or treatment with HIPEC on established protocols.

55 Gastrointestinal Stromal Tumor

Paolo G. Casali, Angelo Paolo Dei Tos, and Alessandro Gronchi

INTRODUCTION

Gastrointestinal stromal tumors (GIST) are mesenchymal neoplasms of the gastrointestinal tract, whose tumor cell's normal counterpart is the interstitial cell of Cajal. This serves as a *pacemaker* of gastrointestinal motility, providing an interface between autonomic nerve stimulation and the muscle layer of the gastrointestinal wall.¹ GISTs are rare cancers, which were defined as a distinct disease in the 1990s, having been classified within smooth muscle neoplasms for decades from their first description in the 1960s.^{2,3} Coincidentally, in 2000, they became targetable by new tyrosine-kinase inhibitors (TKI), given the role played by KIT and platelet-derived growth factor receptor alpha (PDGFRA) in their pathogenesis.⁴⁻⁷ As of today, GISTs serve as an advanced model displaying both potentials and limits of currently available molecularly targeted agents in medical oncology of solid cancers.

From the clinical point of view, surgery is the mainstay treatment when GISTs are localized, and adjuvant therapy is used depending on their risk of relapse. Apparently, adjuvant therapy with TKIs is mainly able to delay relapse, if due to occur, rather than to avoid it. In the advanced disease, TKIs have substantially improved the prognosis of KIT-mutated GISTs and have become standard treatment. They face the major limiting factor of secondary resistance, which affects most patients and is marked by genetic heterogeneity. A minority of GISTs do not harbor mutations to either KIT or PDGFRA genes and, therefore, are called *wild type* (WT). They are less amenable to available TKIs, although their natural history tends to be less aggressive. Their variegated nature adds to the complexity of GISTs as a whole.

In brief, GISTs are more complex than initially believed, whereas targeted therapy has substantially improved their prognosis but is challenged by its apparent inability to eradicate the disease (even minimum residual disease), and by the heterogeneity of the secondary resistance it often gives rise to in the advanced setting. Intense translational and clinical research is underway. All this and the rarity of the disease strongly suggest to refer GIST patients to institutions or networks specializing in their treatment and study.

INCIDENCE AND ETIOLOGY

GISTs are rare cancers. Their crude incidence is suggested to be approximately 1.5 out of 100,000 per year (roughly 5,000 new cases in the United States yearly), with the limitations deriving from the fact that only recently were they identified as a clinicopathologic entity.^{8,9} However, there are a number of small GISTs that are clinically meaningless and generally go undetected. In addition, microscopic GISTs (micro-GIST) might be found incidentally in as many as 10% to 25% of stomachs.^{10,11} The reasons why the vast majority do not give rise to clinically overt diseases are not known, especially considering the fact that most of them harbor the same mutations to KIT and PDGFRA of fully developed diseases, which implies that alterations of these proto-oncogenes are not solely the pathogenetic drivers of GISTs.¹² Thus, the incidence of histologic GISTs may be

much higher than that of clinical cases, which remains low. Prevalence is low as well, although roughly half of clinical GISTs are cured by surgery, and the median survival of advanced GISTs has improved with the use of TKIs and is likely still improving.

GISTs can occur at any age, with a median occurrence at 60 to 65 years. A small minority of GISTs affect children and adolescents: most of them are WT for KIT and PDGFRA and may take place within selected syndromes. In general, GISTs are slightly more incident in males than females. Succinate dehydrogenase (SDH)-deficient WT GISTs typically occur in young females.

No specific causes are known, although the pathogenesis of KIT- and PDGFRA-mutated GISTs has been elucidated in essence. There are some predisposing conditions for WT GISTs, which include the Carney triad (marked by GIST, pulmonary chondromas, and extra-adrenal paragangliomas), the hereditary Carney-Stratakis syndrome (marked by GIST and familial paragangliomas), and type 1 neurofibromatosis (NF-1).¹³⁻¹⁵ Hereditary syndromes driven by germ-line mutations to KIT or PDGFRA are very rare but well recognized.^{16,17}

ANATOMY AND PATHOLOGY

More than half of GIST cases arise from the stomach, one-fourth from the small bowel, roughly 5% from the rectum, and a small minority from the esophagus.⁷ Some GISTs have been labeled as *extragastrointestinal*, apparently arising from the mesentery, omentum, and retroperitoneum; however, it remains unknown whether these are lesions detached from their gastrointestinal origin and/or are metastases from an unknown primary tumor.

Morphologically, GISTs can be made up of spindle cells (in more than two-thirds of cases), epithelioid cells, or both (Fig. 55.1 A,B).¹⁸ Epithelioid-cell GISTs are more common in the stomach and include those that are PDGFRA mutated. Aside from this, there are no major clinical implications in the microscopic aspect of lesions. Importantly, there are no pathologic clues to make a distinction between malignant GISTs and others whose clinical behavior is actually benign. Thus, many GISTs behave as benign diseases as a matter of fact, but this cannot be forecast histologically or molecularly. It follows that all GISTs are currently considered malignant neoplasms, although with a highly variable risk of distant relapse, which is negligible in a significant proportion of them. This is the reason why risk classification systems are generally used in the clinic as prognosticators, being based today on a pathologic factor (i.e., the mitotic count) and two clinical variables (tumor size and tumor site).¹⁹⁻²⁴

Immunohistochemically, the hallmark of most GISTs is their positivity for KIT (CD117) and DOG-1 (Fig. 55.2 A,B).²⁵⁻²⁷ A low proportion of GISTs are CD117 negative, which is typical of PDGFRA-mutated GISTs, but immunohistochemical status does not reflect the mutational status with regard to KIT and PDGFRA, per se, so that it has no concrete predictive value for sensitivity to TKIs. Thus, CD117 has only a meaning in the pathologic differential diagnosis. Given their morphology, GISTs must be differentiated

Figure 55.1 (A) Spindle-cell GIST. (B) Epithelioid-cell GIST.

from other soft tissue tumors of the gastrointestinal wall, including those of smooth muscle and neural origin and desmoid-type fibromatosis, endocrine tumors, melanocytic tumors, lymphomas, etc. Desmin is rarely positive, as opposed to vimentin and CD34. A negative stain for SDHB identifies the subgroup of SDH-deficient WT GISTs.^{28,29}

Molecularly, GIST have become a relatively heterogeneous and complex group of lesions.³⁰ Gain-of-function mutations of the oncogenes located on chromosome 4 (4q12) coding for the type III receptor tyrosine kinases KIT and PDGFRA can be found in approximately 80% of GISTs.^{5,6,31} Pathogenetically, they are the drivers of the disease and, therapeutically, underlie the efficacy of currently used TKIs. They are mutually exclusive and result in the constitutive activation of either KIT or PDGFRA, which normally are autoinhibited, being activated by the binding of their respective ligands (i.e., stem-cell factor [Steel factor] and platelet-derived growth factor A). The activation of the receptor binds two molecules of KIT or PDGFRA (dimerization), giving rise to downstream oncogenic signaling, which for both KIT and PDGFRA involves the RAS/MAPK and the PI3K/AKT/mammalian target of rapamycin (mTOR) pathways (Fig. 55.3). Mutations can be deletions, insertions, and missense mutations. They affect: exon 11 of the KIT oncogene, encoding for the juxtamembrane domain of the KIT receptor, in slightly less than 70% of GISTs; exon 9 of KIT, encoding for the extracellular domain of the receptor, in less than 10%; exon 13 and 17 of KIT, encoding for the intracellular ATP-binding pocket and activation loop domains, respectively, in a small minority of GISTs. Approximately 10% of GIST have mutations homologous to these, which affect PDGFRA (i.e., exon 12, 14, and 18 of the oncogene, with 70% being represented by the

exon 18 D842V mutation). The latter is known for its wide lack of sensitivity to available TKIs, along with a few other rare exon 18 mutations, whereas the deletion of codons 842 to 845 is sensitive. Possibly because of their similarity with different kinds of normal interstitial cell of Cajal, some tumor cell mutations correlate with elective primary sites of origin. In particular, exon 9 mutations of KIT are preferably found in the small bowel, and PDGFRA mutations are found in the stomach.

Approximately 10% to 15% of GISTs are WT for KIT and PDGFRA. They make up a family of tumor subsets with different pathogenetic backgrounds and, to some extent, different natural histories (see Fig. 55.3). Their classification is evolving.^{5,6,31} In essence, as of today, one may identify: (1) SDH-deficient GISTs; (2) neurofibromatosis (NF)-1-related GISTs; or (3) others, including those with the BRAF V600E mutation. In fact, half of WT GISTs are marked by alterations involving the SDH complex, which is crucial for the Krebs cycle and mitochondrial respiratory cell function. Immunohistochemically, these GIST are negative to SDHB staining. A group of them includes *pediatric* GISTs and can be associated with the Carney triad.¹³ In fact, these GISTs tend to arise in children and young adults of the female sex, are gastric and multifocal, can metastasize to lymph nodes, have a rather indolent evolution. When the Carney triad is fully expressed, it includes GISTs, pulmonary chondromas, and paragangliomas. Given the absence of mutations to the SDH complex, a posttranscriptional defect leading to dysfunctions of the SDH complex may be in place. These GISTs are SDHA positive. On the other hand, a group of SDH-deficient GISTs carries germ-line mutations of the SDHA, SDHB, or SDHC units of the SDH complex^{32,33} and may be related to the Carney-Stratakis syndrome.¹⁴ This is marked by

Figure 55.2 Immunostaining for KIT (CD117) and DOG1.

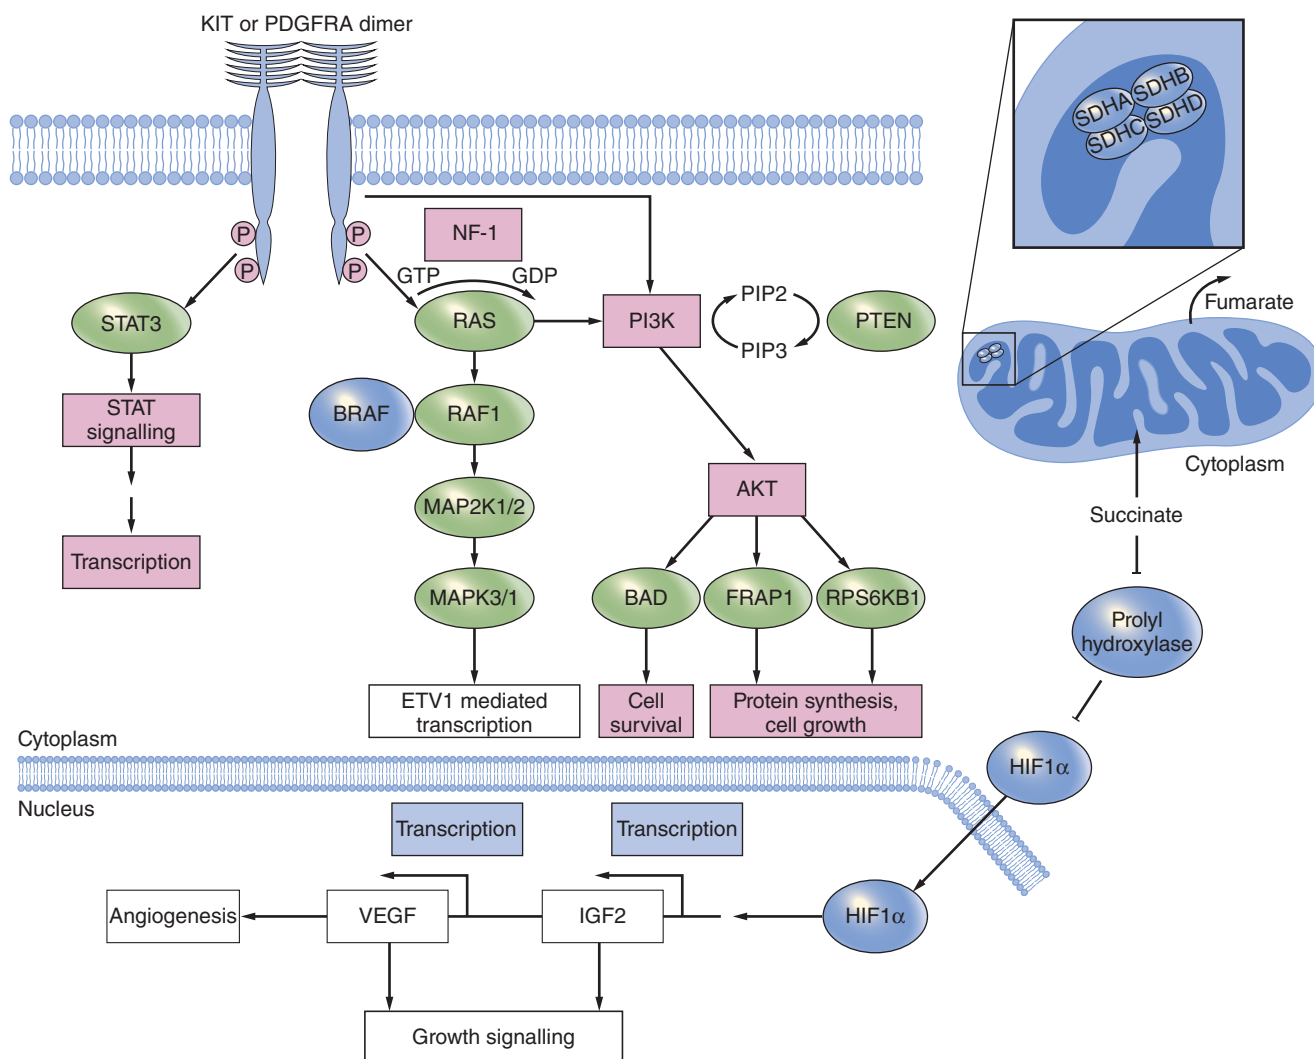

Figure 55.3 Signaling in KIT/PDGFR α -mutated and WT GIST. (From Joensuu H, Hohenberger P, Corless CL. Gastrointestinal stromal tumour. *Lancet* 2013;382:973–983.)

GIST and paragangliomas. Immunohistochemically, GISTs with SDHA mutations are negative to SDHA staining. The median age of these patients is somewhat higher and the female to male predominance is lower, but the course of disease is indolent as well. Then, WT SDHB-positive GISTs can occur in the context of NF-1, and their pathogenetic mechanism is supposed to be the absence of neurofibromin (i.e., the product of the NF-1 gene), which is mutated.^{34,35} This may lead to increased activity of the RAS pathway. GISTs related to NF-1 are typically multicentric as well, and have a rather indolent course, but arise from the small bowel. Of course, NF-1 may coexist with a non-NF-1-related GISTs. Finally, the remaining SDHB-positive GISTs are probably a basket of different conditions: some were reported to have the V600E mutation of BRAF^{36,37} or, more rarely, HRAS, NRAS, and PIK3 mutations.⁵ All this makes the so-called WT GISTs a variegated family of tumors, which can now be identified not only through a negative definition (i.e., by the lack of KIT and PDGFR α mutations), but through immunohistochemical or cytogenetic markers, pointing to specific subsets with different natural histories.

A very rare subset of familial GISTs does exist, being marked by mutations of KIT or PDGFR α affecting the germ line.^{16,17} They parallel mutations found in sporadic GISTs and lead to the multicentric and multifocal occurrence of GISTs. The behavior of these GISTs is variable (i.e., it is often indolent but some lesions turn out to become aggressive). Hyperplasia of interstitial cells of

Cajal can be found, which may entail altered motility of the gastrointestinal tract. Urticaria pigmentosa and other alterations of skin pigmentation may complete the syndrome.

It is then clear how important genotyping has become for GIST patients. In fact, genotyping has an obvious predictive value, which is crucial for all patients who are candidates for medical therapy, whether in the advanced or in the adjuvant setting. In addition, genotyping has prognostic implications, at least given the peculiar natural history of WT GISTs. Finally, genotyping confirms the pathologic diagnosis in KIT/PDGFR α -mutated GIST, or leads to further pathologic and molecular assessments in WT GISTs. Thus, although there are subsets of GISTs with such a low risk of relapse as not to make them candidates for any medical therapy, a mutational analysis is currently felt as a companion to virtually any pathologic diagnosis of GISTs.

SCREENING

GISTs are rare cancers. Therefore, population-based screening policies are unforeseeable. As for all rare cancers, the clinical aim should be a timely diagnosis in the individual patient with symptoms and/or signs of disease. A difficulty thereof is the anatomical tendency of GIST lesions to grow outwards from the gastrointestinal wall, so that they may go undetected for long

Figure 55.4 GIST growing outward of the gastric wall.

periods even when endoscopically explored. However, endoscopic procedures carried out for other reasons may lead to some risk of *overdiagnosis*, even in such a rare disease, when small gastric lesions are incidentally detected. Some of them will be benign entities, and others will be GISTs unlikely to ever grow as to become clinically relevant. Only a minority of them will turn out to be clinically aggressive GISTs caught in their making.

DIAGNOSIS

The outward growth of many GISTs (Fig. 55.4) within the gastrointestinal wall is one of the reasons why several are diagnosed relatively late, either as major abdominal masses or as causes of gastrointestinal bleeding, hemoperitoneum, perforations (Fig. 55.5). Therefore, as many as one-fourth of GISTs are diagnosed in a clinical emergency, often leading to surgical explorations resulting in the unexpected finding of the disease. One-fourth of GISTs are discovered incidentally during diagnostic assessments (whether an endoscopic procedure, ultrasound, or computed tomography [CT] scan) done for other reasons. The remaining are diagnosed because of symptoms of compression from an abdominal mass, or chronic anemia, fatigue, and the like. Therefore, GISTs should be included in the differential diagnosis of abdominal masses. When their pertinence

to the gastrointestinal wall is clear, the possibility of a GIST may be obvious, with a differential diagnosis mainly against epithelial tumors, small bowel endocrine tumors, lymphomas, paragangliomas, etc. Otherwise, retroperitoneal sarcomas and desmoid-type fibromatosis, germ cell tumors, and lymphomas are the main alternatives. Notably, when this is the clinical presentation, surgery is of choice only for some of the possible alternatives within the clinical differential diagnosis. In addition, preoperative treatments may be resorted to even in some of the surgical indications. On top of this, an intraoperative pathologic differential diagnosis is prohibitive. In principle, therefore, a diagnostic core needle biopsy is suggested by many, allowing pathologic diagnosis and, in the case of GIST, a mutational analysis, prior to any surgical exploration. In the case of gastric or rectal lesions, a biopsy can be carried out by means of endoscopic ultrasound, although, for gastric tumors, the risk of perforation should be factored in depending on the presentation. A CT/ultrasound-guided percutaneous biopsy is the other option, apparently with a negligible risk of dissemination if done at a center of expertise, again factoring in the clinical presentation.³⁸ There may remain some cases in which the difficulty of an endoscopic or percutaneous biopsy and the easiness of a surgical exploration would suggest the latter. In general, however, a biopsy prior to any therapeutic planning can minimize the number of abdominal masses undergoing futile surgery.

Figure 55.5 Duodenal GIST with an intratumoral perforation.

Follow-ups after potentially eradicating surgery is aimed at picking up relapses at an early stage. Local relapses are infrequent and tend to develop outwards from the gastrointestinal wall: therefore, an endoscopy is generally not used as a routine follow-up procedure. A CT scan is the most sensitive exam to pick up peritoneal and liver metastases and is recommended. It can be replaced by magnetic resonance imaging (MRI), while ultrasound is much less sensitive on the peritoneum. The maximum risk interval averages 2 to 3 years after surgery or, if an adjuvant therapy was done, after its completion. Long-term relapses are unlikely, although they are occasionally observed, especially in GISTs with a low mitotic rates. All this helps drive rational follow-up policies for potentially cured patients, though there is a lack of any empirical evidence of their effectiveness.³⁹

STAGING

Conventional stage classification is seldom used.⁴⁰ Clinicians mainly distinguish localized from metastatic disease and, if the disease is localized and amenable to complete surgery, quantify the risk of relapse.^{20,22,24}

Current risk classification systems are based on the combination of mitotic count, tumor size, and site of origin. Indeed, the mitotic count is the main prognostic factor, proportionally correlating to the risk of relapse. Its downside has turned out to be its possibly low reproducibility rate, but clearly this can be higher if the pathologist is aware of its importance in driving treatment choices. Tumor size is the next prognostic factor. On one side, it singles out very small gastric lesions (<2 cm), which may undergo watchful surveillance if incidentally discovered endoscopically. On the other, it highlights lesions in excess of 5 to 10 cm, which have a worse prognosis. With regard to the primary site, gastric lesions have a better prognosis than small bowel and rectal GISTs. Thus, the combination of these three factors allows one to forecast a risk of relapse by using tools such as the Armed Forces Institute of Pathology (AFIP) risk classification, the Memorial Sloan Kettering Cancer Center (MSKCC) nomogram, or the contour maps. The contour maps have the advantage of treating both the mitotic rate and tumor size as continuous variables as they are, so that the accuracy is increased especially for intermediate-risk cases (Fig. 55.6). Also, reproducibility issues become less crucial by factoring mitotic count as a continuous variable. In addition, contour maps segregate the prognosis

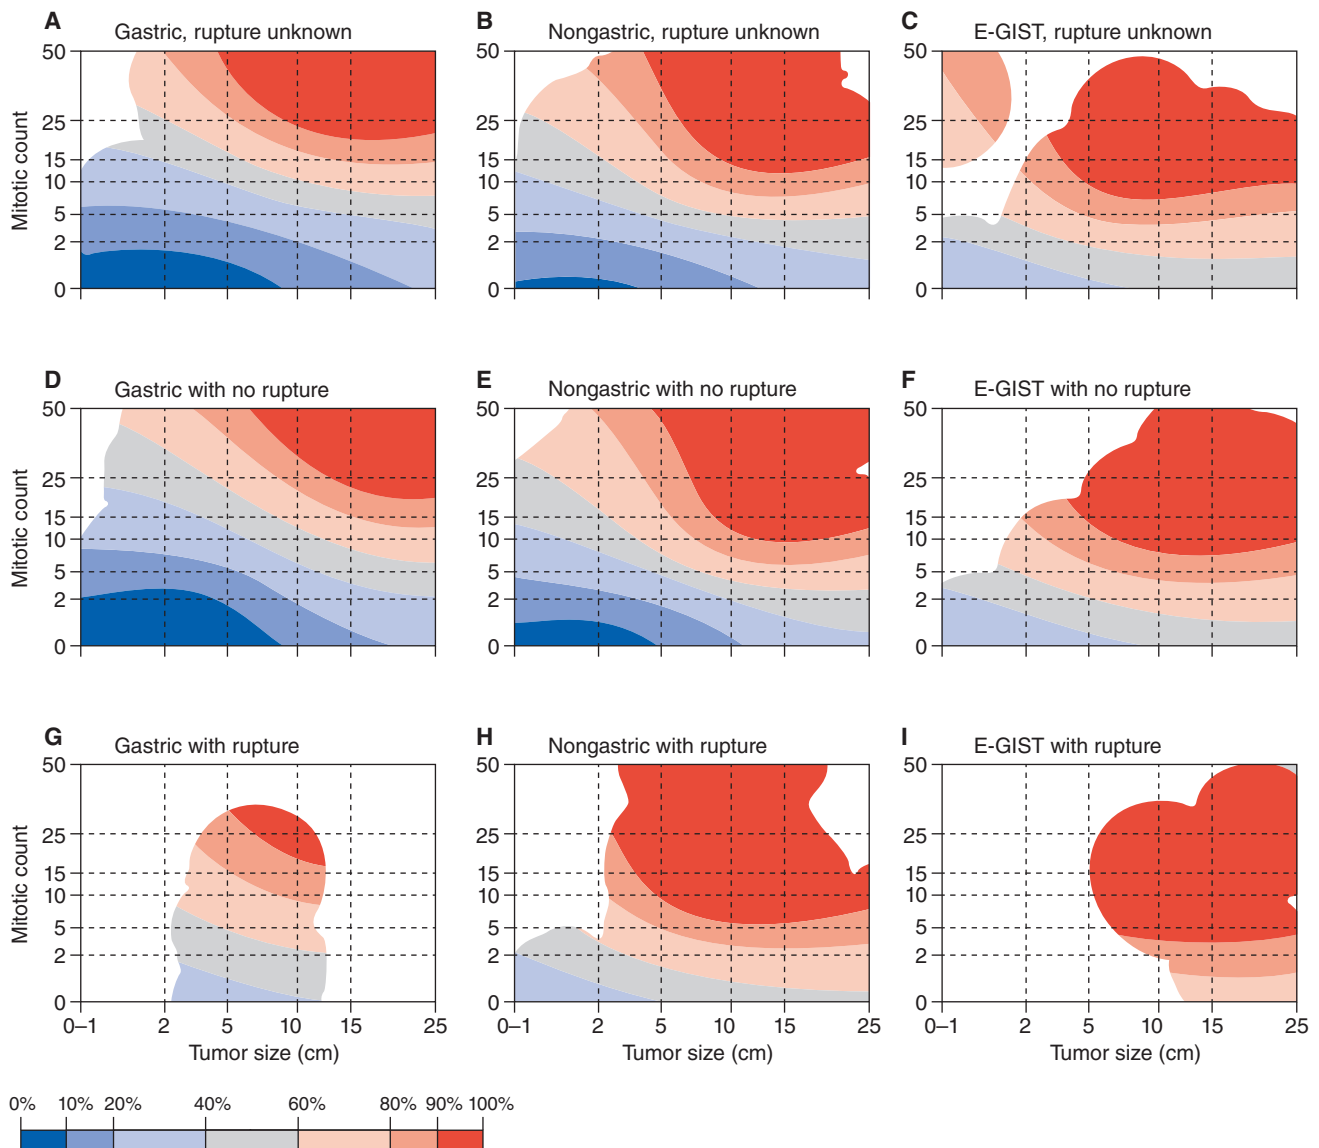

Figure 55.6 Contour prognostic maps in localized GISTs. (From Joensuu H, Vehtari A, Riihimäki J, et al. Risk of gastrointestinal stromal tumour recurrence after surgery: an analysis of pooled population-based cohorts. *Lancet Oncol* 2012;13:265–274.)

of lesions that underwent tumor rupture, which is a highly adverse prognostic factor in diseases anatomically facing the peritoneum.⁴¹

The natural history of advanced GISTs is marked by their potential extension to the peritoneum and/or the liver. Thus, a CT scan is the staging procedure of choice to rule out metastatic disease. Lung metastases are rare, with the possible exception of rectal GISTs, although a chest CT scan is generally used to extend a staging workup to lungs and the mediastinum. Bone metastases are possible, but they are usually confined to the very advanced stages of disease, so that the skeleton is not routinely assessed in the lack of symptoms.⁴² Other sites of distant metastases are exceedingly rare. Lymph node regional metastases are not typical of GISTs, as for mesenchymal tumors in general, with the remarkable exception of WT GISTs occurring in children and/or within syndromes. In addition, all *syndromic* GISTs may be multifocal and multicentric.^{43,44} This is not tantamount to metastatic spread, being rather a marker of their inherent natural history. All these features of the natural history of GISTs drive staging procedures, in addition to the potential for other syndromic correlates, depending on the presentation.

MANAGEMENT BY STAGE

Localized GISTs with no evidence of distant metastases are treated with surgery, followed by adjuvant medical therapy if the risk of relapse is significant. This treatment strategy capitalizes on the consolidated curative potential of surgery and prolongs the relapse-free interval of patients who are not eradicated. When surgery is unfeasible or could be made less mutilating or easier through downsizing, medical therapy is used if the genotype is sensitive to imatinib, possibly followed by surgery and the completion of a medical adjuvant treatment if the risk of relapse is significant. When the disease is metastatic, medical therapy with TKIs is standard treatment and should be maintained indefinitely. Surgery of metastatic residual responding disease can be used when reasonably feasible, but its added value prognostically is unproven. When imatinib fails and/or is ineffective, other available TKIs and judicious use of surgery of limited progression are resorted to (see Table 55.1 for conventionally used agents). This treatment strategy has substantially improved the prognosis of advanced GIST patients by increasing median survival in terms of years if compared to any historical series, with a proportion of patients, limited though it may be, becoming long-term progression-free survivors.

When the disease is localized, surgery is the treatment mainstay. Indeed, all GISTs ≥ 2 cm in size should be resected when possible, because none of them can be considered *benign*. The management of GISTs < 2 cm in size is more questionable.⁴⁵⁻⁴⁷ Although the low risk of progression of GISTs < 2 cm leads to the recommendation of a conservative approach, a reliable mitotic

index cannot be determined by biopsy or fine-needle aspiration (FNA), thus preventing the identification of those at higher risk. Therefore, both observation and resection for GISTs 1 to 2 cm can be considered, and the risks and benefits of one versus the other should be discussed with the patient. The endoscopic resection of small gastric GISTs could be an option in these presentations. Risks of perforation may be low, although the decision is made on a case-by-case basis. Regardless of their size, any small GIST that is symptomatic (e.g., bleeding from erosions through the mucosa) or increases in size on serial follow-up should be resected.

A laparotomic or laparoscopic/laparoscopy-assisted resection of primary GISTs should be performed following standard oncologic principles. On laparotomy/laparoscopy, the abdomen should be thoroughly explored to identify and remove any previously undetected peritoneal metastatic deposits.⁴⁸⁻⁵¹ Although primary GISTs may demonstrate inflammatory adhesions to surrounding organs, true invasion is not frequent. The goal of surgery is R0 excision. A macroscopically complete resection with negative or positive microscopic margins (R0 or R1 resection, respectively) is associated with a better prognosis than a macroscopically incomplete excision (R2 excision).^{52,53} Available series have not clearly shown that R1 surgery is associated with a definitely higher risk of local failure, so that the decision whether to reexcise a lesion already operated on with microscopically positive margins is doubtful, aside from the fact that sometimes a reexcision may not be technically foreseeable in the gastrointestinal tract. An exception are GIST of the rectum, where microscopically positive margins are clearly associated with a higher risk of local failure.⁵⁴ In general, local relapse after R0 surgery is very unlikely in GISTs. Of course, the margins of a big lesion toward the peritoneum will not be covered by any clean tissue, and this may well be the main reason for the high peritoneal relapse rate of large tumors even after complete surgery. Tumor rupture or violation of the tumor capsule during surgery are associated with a very high risk of recurrence, and therefore should be avoided.⁴¹ Some clinicians approach ruptured GISTs as already metastatic, although there may be different kinds of *rupture*, possibly leading to different risk levels. A lymphadenectomy is not routinely required, because lymph nodes are rarely involved (in adult patients) and are thus resected only when they are clinically suspect.

In general, surgery is a wedge or segmental resection of the involved gastric or intestinal tract, with margins that can be less wide than for an adenocarcinoma. Sometimes, a more extensive resection (e.g., total gastrectomy for a large proximal gastric GIST, pancreaticoduodenectomy for a periampullary GIST, or abdominoperineal resection for a low rectal GIST) is needed. In the rare syndromic GIST (either SDH deficient or NF-1 related), tumors are often multifocal and confined either to the stomach (SDH-deficient GIST) or the small bowel (NF-1-related GIST). The extent of surgery should be decided on a case-by-case basis, taking into account the risk of recurrence, the lack of benefit from currently available TKIs, and the actual behavior of the underlying disease.⁵⁵

Adjuvant medical therapy with imatinib was demonstrated to substantially improve relapse-free intervals, although with a trend to lose the benefit in a time span of 1 to 3 years from the end of therapy.⁵⁶⁻⁵⁸ This was shown through randomized trials that compared 1 and 2 years of adjuvant therapy with imatinib versus no adjuvant therapy, and 3 years versus 1 year of adjuvant therapy with imatinib. As of today, the suggestion from these studies is that adjuvant therapy with TKIs can delay, but probably not avoid, a relapse, if this is due to occur. This correlated with a survival improvement in one trial⁵⁷ and with a trend to improvement of a potential surrogate for survival in another,⁵⁸ where the surrogate was survival free from changing the original tyrosine kinase inhibitor (TKI)—in practice, survival without secondary resistance. In fact, secondary resistance is the limiting factor of TKIs in the advanced setting, so that an adjuvant therapy will be beneficial as long as it either avoids recurrences or at least prolongs freedom from secondary resistance, but by no means shortens it. Thus, the risk of any detrimental effect was ruled out for adjuvant therapy durations up to 3 years. In this

TABLE 55.1

Standard Medical Agents Currently Used in GIST

■ Imatinib

- 400 mg by mouth daily
- Possibly 800 mg by mouth daily, in case of:
 - Exon 9 KIT-mutated GIST
 - Progression on imatinib 400 mg

■ Sunitinib

- 50 mg by mouth daily for 4 wks every 6 wks
- 37.5 mg by mouth daily continuously

■ Regorafenib

- 160 mg by mouth daily for 3 wks every 4 wks

sense, going beyond 3 years would seem logical, given the tendency to lose the benefit after 1 to 3 years from stopping adjuvant therapy, but such a policy should be validated by clinical trials ruling out any adverse effect on secondary resistance. Results from clinical studies on longer durations of adjuvant therapy are therefore expected. Currently, adjuvant therapy is recommended for 3 years and is reserved for patients with a significant risk of relapse, as long as the benefit in absolute terms will be higher as the risk increases, as is the case with all adjuvant therapies. In a sense, the lack of a tangible impact on the long-term relapse rate encourages one to exclude relatively low-risk patients, which is, to some extent, at odds with what is done with adjuvant cytotoxic chemotherapy in some solid cancers. This said, the magnitude of risk that is worth an adjuvant therapy with imatinib for 3 years may well be subject to a shared decision making with the individual patient, and, as a matter of fact, is generally placed above 30% to 50%. Logically, a benefit can be expected for patients whose genotype is potentially sensitive to imatinib.⁵⁹ In practice, this leads to the selection of all patients with a KIT-mutated GIST or a PDGFRA-mutated sensitive GIST (with the exception of the D842V exon 18 mutation and the few others which are insensitive *in vitro* and *in vivo* to imatinib). Given the benefit shown with the use of a double dose of imatinib (800 mg daily) for advanced GIST patients with an exon 9 KIT-mutated GIST,⁶⁰ such a dosage can be selected for them, although there is a lack of any formal demonstration in the adjuvant setting. WT GISTs are much less sensitive to imatinib, and adjuvant studies

are lacking with other TKIs, which may be potentially more active. Even more importantly, the natural history of WT GISTs is often less aggressive. These are the reasons why many clinicians currently do not select WT GISTs patients for any adjuvant treatment.

Given the extensive use of adjuvant therapy with imatinib in the high-risk populations and the activity of the drug, several recent multi-institutional retrospective series have questioned the need for extensive resections such as pancreaticoduodenectomy, abdominal perineal resection, or total/proximal gastrectomy, when tumor downsizing can be likely achieved with a preoperative medical treatment. In practice, preoperative imatinib can shrink gastric, periampullary, or rectal GISTs to such an extent as to allow more limited excisions (wedge gastrectomy, excision of periampullary lesions, transanal/perineal resection of rectal GISTs, respectively), and imatinib can then be continued postoperatively to complete the *adjuvant* treatment (Fig. 55.7). Thus, if extensive surgery is required for complete tumor removal, preoperative imatinib should be considered.⁶¹⁻⁶⁴ In addition to this, there are some big abdominal masses that may be felt by the surgeon as implying a significant risk of tumor rupture during surgery, which can be treated with preoperative imatinib. Because downsizing is the clinical end point in these cases, the duration of pre-operative medical therapy is generally 6 to 12 months, which corresponds to the time interval when the maximum degree of tumor shrinkage was shown to occur in studies on advanced GISTs.⁶⁵ In addition, mutational status is important in order to select patients likely to respond to imatinib,

Figure 55.7 (A) Tumor shrinkage of a gastric primary GIST after 12 months of preoperative imatinib, (B) allowing for a sleeve gastrectomy plus splenectomy and liver resection with preservation of most of the stomach after resection.

and tumor response should be monitored closely. Positron-emission tomography (PET) scans are a resource, because they can demonstrate tumor responsiveness in a matter of weeks.

Syndromic GISTs can present with multifocal and/or multicentric disease, which may imply delicate surgical decisions. Thus, in WT GISTs, such as those occurring in children and young adults or in NF-1 patients, one should take into account the indolent behavior of many lesions and the possible presence of hyperplasia of the interstitial cells of Cajal on one side, and the possibility that single lesions may be aggressive on the other. Surgery should judiciously factor in all this. In addition, the relative lack of sensitivity of WT GISTs to available TKIs may suggest to resort to surgery more liberally than is currently done with KIT-mutated GISTs.

With regard to the highly rare syndromes of familial GISTs from germ-line mutations of KIT or PDGFRA, treatment is challenging and may involve resorting to surgery and/or TKIs depending on the behavior and extent of clinically relevant lesions.

When the disease is metastatic or locally advanced, medical therapy is the best choice and is currently based on imatinib continued indefinitely.⁶⁶⁻⁶⁹ However, given the limiting factor of secondary resistance, some clinicians prefer to surgically resect some highly localized first distant relapses, thus delaying the start of imatinib to a subsequent relapse. It is unproven whether this approach may delay progression, its rationale being to delay the onset of time to secondary resistance by delaying the onset of any use of TKIs. Theoretically, the downside may be starting medical therapy with a higher tumor burden, which was shown to be related to a shorter time to secondary resistance to imatinib.

In fact, initial tumor burden is virtually the only prognostic factor in the metastatic GIST patient starting imatinib.⁷⁰ On the other hand, although above 80% overall, the probability of response is strictly correlated with the mutational status, which is, therefore, the main predictive factor.⁷¹⁻⁷³ KIT-mutated GIST are responsive in most cases, including the most frequent genotype, marked by mutations of exon 11. This applies also to patients who underwent adjuvant imatinib and who did not experience tumor relapse during the adjuvant period, so that these patients are currently approached the same way as those who have not been already exposed to imatinib. The standard daily dosage of imatinib is 400 mg. However, there are data derived from retrospective subgroup analyses that suggest progression-free survival is better with doses higher than 400 mg (i.e., 800 mg daily) for exon 9 KIT-mutated GIST patients.⁵⁰ Thus, many institutions treat these patients with 800 mg. PDGFRA-mutated GIST patients can be sensitive to imatinib as well, with the remarkable exception of the D842V mutation, which is the most frequent amongst PDGFRA mutations, and a few others. WT GISTs are less sensitive to imatinib, which may, however, be active in some patients. Sunitinib is an alternative option, because it was shown to have some activity in WT GISTs.⁷⁴ Generally, the clinical decision in WT GISTs, and of course PDGFRA D842-mutated patients, takes into account the natural history of these subtypes, which is often less aggressive than in KIT-mutated GISTs. Thus, surgical options, including ablations, may be resorted to when the relapse is limited. However, in sensitive genotypes medical therapy is an option even when surgery is feasible, and any decision on surgery is usually delayed to when the tumor response has been established. This allows for the possibility of being certain about a patient's responsiveness to a medical therapy that will need to be prolonged indefinitely because the disease is metastatic.

In fact, a discontinuation trial showed that stopping therapy after 1, 3, or 5 years is followed by progression in a matter of months.⁷⁵ It is true that reestablishing therapy generally leads to a new response, but its quality may be inferior to the previous one.⁷⁶ In any case, intervals to progression would be remarkably short, and an untenable *stop-and-go* treatment policy would be the result.

Imatinib is generally well tolerated, with fatigue, edema, mild diarrhea, and anemia as frequent complaints, along with less frequent toxicities, such as neutropenia, skin rash, and others.⁶⁷⁻⁶⁹

Clinical wisdom needs to be exercised in order to maintain dose intensity vis-a-vis side effects.⁷⁷ The number of patients truly intolerant to imatinib should be exceedingly low.

Secondary resistance is the limiting factor of imatinib, with a median time to the event averaging 2 years in the frontline advanced setting. One cannot rule out that current patients, who are generally put on therapy with lower tumor burdens, may show improved progression-free survival intervals over the earliest series. More importantly, the range of time to secondary resistance is wide, with a limited proportion of patients, averaging 10%, who become long-term progression-free survivors. Currently, there are no known prognostic factors for long-term progression-free survivorship, excluding the mutational status, which affects tumor response to imatinib, and tumor burden at the onset of imatinib therapy, which affects the duration of response. The group of long-term progression-free survivors may thus represent either just the "tail" of a curve driven by the stochastic mechanisms of secondary resistance, or the result of specific genomic profiles, still to be elucidated.

In an attempt to downsize tumor burden, thus potentially prolonging time to secondary resistance, surgery of residual responding disease has been resorted to in many institutions, and its results were retrospectively, but not prospectively, evaluated, with the exception of an underpowered randomized prospective study in patients who had only peritoneal disease.⁷⁸⁻⁸³ These case series analyses showed a better prognosis for patients undergoing surgery, but a selection bias may well explain the results. Prospective trials have not been successful; therefore, the decision whether to surgically excise metastatic lesions responding to imatinib is currently left to a shared decision making with the patient in conditions of uncertainty. Of course, clinical presentations are manifold, and sometimes the easiness of the surgical resection is the main factor leading to the decision, and vice versa. In general, many institutions currently avoid resorting to major surgery for responding metastases. In any case, only patients amenable to complete resection of all lesions should be candidates for this kind of surgery. In this sense, surgery may be less often indicated in peritoneal compared to liver metastases, because the former are frequently underestimated by available imaging modalities and the selection of completely clearable tumors is less feasible. However, the clinician must be aware that imatinib needs to be continued after surgery, even if surgery was complete. In fact, some patients enrolled in the discontinuation trial of imatinib had had a complete excision of their metastatic lesions.⁷⁴ In addition, surgery of metastatic GISTs was never proved to be eradicating in the pre-imatinib era.⁸⁴

Progression during therapy with imatinib is often due to secondary resistance, which essentially is marked by the occurrence of new mutations to the same primarily mutated oncogene, or, less frequently, oncogene amplifications or alterations of alternative pathways.⁵ It is left to elucidate whether these secondary mutations should be biologically viewed as developing *de novo*. Secondary mutations entail such consequences as to lower the binding capacity of the KIT or PDGFRA receptor for imatinib and/or to circumvent its inhibiting action by escape mechanisms.⁸⁵ It was demonstrated that secondary resistance can be heterogeneous, so that more mutations can be detected in different lesions, or even within the same lesion.^{86,87} Of course, this is a major limiting factor for second-line agents targeting KIT or PDGFRA. Secondary mutations in KIT-mutated GISTs are relatively limited in number, affecting exons 13 and 14, which encode the ATP-binding pocket, or exons 17 and 18, which encode the activation loop. Many resistant PDGFRA-mutated GISTs acquire the D842V mutation, which encodes for the activation loop of the receptor.

Clinically, the progression may be *limited* in a substantial proportion of cases. This means that progression is radiologically evident only in one or a few lesions, with the others still progressing. A typical clinical pattern is the *nodule within the nodule* (i.e., a small hyperdensity within a responding hypodense lesion on CT scan).⁸⁸ Given the scope of activity of further-line therapies, many clinicians now tend to treat limited progression conservatively from the medical point of view, resorting to selected surgical or

ablative procedures to get rid of the progressing component of the disease, while continuing imatinib for the remaining. This might delay the moment when the first TKI is switched to a second-line one. Though this policy is not based on prospective clinical studies, it makes sense in the economy of advanced GISTs following the introduction of TKIs. Clearly this does not apply to *generalized* progressions.

Radiologic progression should be confirmed, taking into account the peculiarities of tumor response patterns in GISTs undergoing TKIs. Furthermore, before attributing progression on frontline imatinib to molecular secondary resistance, one should rule out any lack of patient compliance with therapy, which may often go unnoticed and even be underappreciated by the patient. Another mechanism leading to resistance can lie in changes of the pharmacokinetics of the drug. There is evidence that pharmacokinetics can undergo variations with time, in addition to being variable across individuals.⁸⁹ This has led to the evaluation of the importance of maintaining target plasma levels of imatinib.⁹⁰ There are limitations to the standardization of such assessments, and available data pointing to a correlation with progression-free survival are retrospective in nature. Thus, at the moment, we lack any convincing formal demonstration that pharmacokinetics is a factor able to personalize medical therapy (i.e., to drive changes in drug dosages in the lack of evident progression). However, available evidence also suggests that it can well be a variable with many orally administered targeted agents. At least, plasma levels may be assessed in the single patient: in case of clinical progression, to rule out that a major pharmacokinetic issue does exist at that stage; in case of unexpected side effects; and in case of comedications potentially able to interfere with the drug metabolism.

In the case of clinical progression with imatinib 400 mg daily, an option widely used is to increase the dose to 800 mg daily. This proved temporarily successful in a limited proportion of patients crossing over to the higher dose in randomized trials that compared 400 mg with 800 mg as frontline therapy for advanced GISTs.⁹¹ When valuing this benefit, one should probably discount patients who had an exon 9 mutation and who started with 400 mg, and possibly some patients failing to comply with therapy, whereas other patients may have benefited due to the correction of pharmacokinetics problems.

Standard second-line therapy is sunitinib, which is a TKI inhibiting KIT and PDGFRA but also displaying antiangiogenic activity by the inhibition of vascular endothelial growth factor receptor (VEGFR)1, 2, and 3. It was shown to be effective at increasing progression-free survival by 5 months in a randomized trial versus placebo in patients failing (or intolerant) to imatinib.⁹² Its molecular profile is such as to include activity on exon 9 KIT mutations as well as on secondary mutations of regions coding for the ATP-binding pocket, thus potentially covering mutations which are, respectively, less affected or not affected by imatinib.⁹³ What limits the potential of molecular prediction in further-line therapies of GISTs is basically the heterogeneity that often underlies secondary resistance, so that the presence of a secondary mutation is unlikely to be alone, although potentially sensitive to available agents. However, the activity of sunitinib against some secondary mutations and probably its antiangiogenic activity underlie its clinical efficacy after failing to imatinib. Its tolerability profile is less favorable, with fatigue and hand-foot syndrome as its main side effects, variable though they may be across patients. Although the clinical trial evaluated a regimen of sunitinib given 50 mg daily for 4 weeks, with a 2-week rest, a continuous regimen with a daily dose of 37.5 mg can be used as well.⁹⁴

Regorafenib, another TKI with activity on KIT and PDGFRA as well as VEGFR1, 2, and 3, and thus with antiangiogenic properties, is standard third-line therapy for advanced GIST patients. In fact, it was shown to be effective as a third-line therapy in patients failing both imatinib and sunitinib, by providing a median advantage of 4 months of progression-free survival over placebo in a randomized clinical trial.⁹⁵ Its tolerability profile is close to sunitinib,

with hand-foot syndrome, hypertension, fatigue, and diarrhea as main side effects.⁹⁶

An observation made in this trial was the persistence of some activity when therapy was carried on beyond progression.⁹⁷ In other words, a subset of patients, although arbitrarily selected by investigators on clinical grounds, went on with therapy beyond their first progression, achieving a second progression-free interval that approximated the previous one. This would suggest that a subset of progressing patients have a disease that might be slowed down by continuing the TKI in spite of the progression. This observation likely applies to all TKIs, at least in selected patients, and is worth testing prospectively by developing criteria to single out those patients who are more likely to benefit. In general, this parallels the clinical feeling that stopping any kind of TKI may accelerate tumor progression, even when resistance to that TKI has been established. Indeed, a criticism that was made to placebo-controlled trials on new TKIs in GIST is the lack of any tyrosine kinase inhibition in the control group, possibly worsening its outcome in comparison to what could happen by continuing the TKI already in use or by rechallenging the disease with a TKI used earlier.

In fact, in anecdotal cases and also in a small randomized clinical trial, it was shown that rechallenging a progressing GIST patient with TKIs used at an earlier stage can be beneficial, at least temporarily.⁹⁸ In other words, reestablishing imatinib in patients who underwent the drug as frontline therapy and then switched to others results in a benefit in terms of progression-free survival that is not far from what is achievable with further-line agents. One may speculate that there is a process of reexpansion of tumor clones that were sensitive to imatinib and might have been narrowed by the selective pressure of the drug, as long as resistant clones were emerging.

Following third-line therapy, there is no standard option at the moment, aside from rechallenge, and clearly patients are eligible for clinical studies on new agents. New drugs investigated in currently ongoing trials include other TKIs targeting KIT and PDGFRA; agents targeting downstream pathways (e.g., PI3K/AKT); agents targeting heat shock proteins, given their chaperone function for KIT and PDGFRA; among others. Clearly, agents with a mechanism of action other than imatinib, sunitinib, and regorafenib try to address the limiting factor of the heterogeneous nature of secondary resistance. Combinations of agents with different mechanisms of action are tried as well, although their added toxicity may be prohibitive even when they are reasonably well tolerated as single drugs. Future directions might try to exploit molecular diagnostics such as the *liquid biopsy* (i.e., the assessment of secondary mutations on circulating DNA shed by tumor cells). The sensitivity of this technique for primary and secondary mutations of GISTs has been demonstrated.⁹⁹ Thus, it looks promising for the future, to allow a degree of molecular personalization of therapy, whether following secondary resistance or before it establishes clinically, as a means to avoid or delay its occurrence. Combinations or rotations of TKIs might be tested, rationally driven by liquid biopsies. This could exploit the peculiarities of resistance seen with TKIs in GISTs. In fact, the efficacy of treatment beyond progression and of rechallenge suggests that sensitive and resistant clones may fluctuate within the tumor load, depending on the selective pressure they are exposed to. This would be consistent with the model of a *liquid resistance*, which, clinically, could be exploited by employing new strategies as from the upfront approach with TKIs.

A methodologic issue in the medical therapy of GISTs with all TKIs lies in the peculiar patterns displayed by tumor response as compared to those observed with standard cytotoxic chemotherapy of solid cancers and lymphomas.^{100,101} These patterns of tumor response are marked by the possible lack of tumor shrinkage in the face of substantial changes in tumor tissue and tumor metabolic activity. Although most observations derive from imatinib in frontline therapy, in essence, they regard all TKIs, the main difference being possibly the weakness of tumor response

to further-line therapies, so that some of these aspects may look less clear cut in the further-line therapy setting as opposed to the frontline. Under these patterns of tumor response, first of all, in the presence of symptoms, a subjective response may take place very early. In a matter of days, if not hours, after starting an effective TKI, a symptomatic patient may well feel a clear degree of subjective improvement. As far as imaging is concerned, this is paralleled by metabolic response as assessed through a fludeoxyglucose (FDG)-PET scan.¹⁰² A positive PET scan may turn negative in a few days. Of course, this does not correspond to the disappearance of the tumor lesion, but rather be the consequence of the metabolic *switch off* that the tumor undergoes when an effective TKI targets its cells. The reverse is true as well, so that any stop of therapy rapidly entails a *switch on* of functional imaging. Again, this does not correspond to clinical progression, which would follow only for longer interruptions of therapy. This should be taken into account when assessing functional tumor response, because, for instance, any lack of compliance with therapy in the days the exam is made might affect metabolic response as detected through PET scanning. For example, metabolic switch on was observed by PET scans performed during the 2 weeks off of therapy with sunitinib. In principle, this adds to the feeling that TKIs need to be maintained in order to preserve tumor response, in the context of a *clinically cytostatic* effect. It goes without saying that when a PET scan has become negative, the tumor lesion will not be visible to functional imaging, so that a CT scan, MRI, or ultrasounds need to be used in order to appreciate the evolution of tumor lesions. The radiologic response, as assessed through CT scans and MRI, is marked by tumor shrinkage and/or changes in tumor tissue. Tumor shrinkage may well appear very early, but, in some cases, it is lacking in the early phases of treatment, or even later on, so that tumor lesions look unchanged dimensionally. Sometimes tumor size may even increase. In these cases, however, if a response is in place, the radiologic aspect will show substantial changes to the tumor tissue. On a CT scan, this means a decrease in density of responding lesions, with decreased contrast enhancement. On an MRI, it entails a hypointense signaling on T1-weighted images and hyperintense on T2-weighted images, and decreased contrast enhancement. These changes are substantial in GIST patients undergoing frontline therapy with imatinib, so that recording tumor response is generally unchallenging for the clinician, provided tumor shrinkage is not the only criterion. Signs of nondimensional response may prove less obvious when the tumor response is less clear cut, as with further-line therapy with TKIs. Functional imaging may help, although it is exposed to the same limitations as well if the response is less striking. However, when the response is overt, the main shortfalls of nondimensional tumor response assessments lie in the difficulty to standardize reproducible (i.e., reliable) instruments, as is needed in clinical trials. In this sense, Response Evaluation Criteria in Solid Tumors (RECIST) criteria for tumor response assessment are based on the measurement on one diameter of selected target lesions and, thus, have a good record of reproducibility.¹⁰³ However, their *validity* is, by definition, unsatisfactory in the presence of a nondimensional response. Choi criteria were worked out in GISTs to accommodate these patterns of response, by factoring tumor hypodensity on CT scans in addition to a decrease in size.¹⁰⁴ Their validity in predicting progression-free survival was demonstrated and compared favorably with RECIST criteria, while paralleling functional imaging with PET scanning. Then, aside from the need to use easily reproducible instruments in the research setting, for the clinician the message coming from the GIST model is simple, inasmuch as it points to the existence of nondimensional patterns of tumor response, which can be easily highlighted through CT scans and MRI on one side and through functional imaging with PET scan on the other. One should be aware that the meaning of a radiologic response through CT scans or MRI is deeply different from metabolic response assessed through a PET scan. In fact, a PET

Figure 55.8 Pathologic tumor response of a GIST lesion following therapy with imatinib.

scan measures the biological effect of a TKI on the tumor cells very early, but does not necessarily imply any anatomical change in the tumor. On the contrary, CT scans and MRI detect actual changes in the tumor tissue, which correspond to pathologic signs of tumor response. These were found to take shape in terms of a myxoid degeneration widely affecting responding tumor lesions, with signs of apoptosis (Fig. 55.8). A variable proportion of vital cells may be detected, especially to the periphery of lesions (pointing in principle to the prospects of regrowth in case of discontinuation of the TKI). In this sense, a nondimensional tumor response does not mean just *absence of progression*; indeed, it is all about an actual pathologic response, with major changes to the tumor tissue. Of course, all tumor changes one can see when a tumor response is in place have their counterparts when the tumor progresses. Thus, increased tumor density and contrast enhancement on a CT scan will mark tumor progression, with or without an increase in tumor size. This may well affect just a portion of the tumor lesions, such as its periphery or a small part (as is the case with the *nodule within the nodule*). In brief, the quality of the tumor tissue should be observed, in addition to its size, in order to detect both response and progression in GISTs undergoing a TKI. Whatever the response pattern, whether dimensional or not, a tumor response on a CT scan or MRI says that the tumor is undergoing pathologic changes that clearly correlate with the prognosis. In fact, both dimensional and nondimensional tumor responses have clearly correlated with improved outcome in clinical trials, as opposed to progression. Only secondary resistance, or treatment interruption, will terminate a dimensional or nondimensional tumor response, with radiological signs that, as said, will be dimensional or nondimensional as well.

PALLIATIVE CARE

The natural history of GISTs that are not cured by initial surgery is dominated by abdominal spread involving the liver and the peritoneum. Liver failure as well as intestinal and urinary obstructions are thus the main palliative challenges. This may well carry the need of palliative surgery in selected patients. Extra-abdominal metastases are occasionally seen, mainly to the bone, and can require palliative irradiation. A systemic sign such as fatigue may add to asthenia induced by anemia as well as directly by TKIs. In fact, the existence of three lines of standard medical therapy, the potentials of rechallenge, and the availability of many agents of interest, either within clinical studies or among TKIs developed for other diseases, lead to treating many GIST patients with molecularly

targeted therapy even in the very advanced stages of disease. In this sense, the usual palliative challenges of abdominal malignancies meet the new palliative challenges posed by the use of TKIs, which revolutionized the field of the disease.

Indeed, all phases of treatment of GIST are currently a model for the medical oncology of new molecularly targeted agents. The model continues to shed light on their potentials in solid cancers as

well as on their current limitations. It also demonstrates how clinical methodology is deeply affected by these agents, not only for medical oncologists, but for all members of the multidisciplinary cancer team, from surgeons to palliative physicians. Interestingly, the model of GISTs shows how a multidisciplinary approach remains crucial in solid cancers, in all phases of disease, and in the era of molecularly targeted therapies, too.

56 Molecular Biology of Colorectal Cancer

Ramesh A. Shivdasani

INTRODUCTION

The cumulative lifetime risk of developing colorectal cancer (CRC) in the United States is about 6% (www.cancer.gov/statistics) and increases about fourfold in persons with a family history of CRC. Fewer than 5% of cases, however, occur in patients with inherited predisposition syndromes. Most CRCs are therefore considered sporadic, although 20% to 30% of cases might have a familial basis despite the absence of a known germ-line defect, and genomewide association (GWA) studies reveal at least 20 alleles that elevate the risk of developing CRCs. Characteristic somatic mutations, DNA repair defects, chromosomal instability, and epigenetic alterations promote the disease. Predisposing conditions and somatic mutations profoundly inform the molecular understanding of CRCs and serve as a paradigm for the genetic basis of cancer.

MULTISTEP MODELS OF COLORECTAL TUMORIGENESIS

The genetic basis of CRC is best appreciated in light of the adenoma–carcinoma sequence. CRCs invariably arise within benign precursor polyps that show epithelial overgrowth, dysplasia, abnormal differentiation, and, sometimes, foci of tissue invasion. Pedunculated polyps are the most significant precursor lesions, with those larger than 1 cm harboring about a 15% risk of progressing to carcinoma over 10 years; endoscopic removal of these adenomas reduces CRC incidence and mortality.¹ The prevalence of polyps in the United States, estimated at up to 50% by age 70,² dwarfs the 6% lifetime risk of CRCs because few adenomas progress to invasive cancer and the successive aberrations that promote invasion and malignancy take 1 to 3 decades to accumulate.³

Nonclassical adenomas, such as hyperplastic polyps, were previously thought to have little potential to spawn invasive CRCs, but two serrated precursor lesion forms are now recognized.⁴ Serrated adenomas with cytologic dysplasia occasionally evolve into common CRCs with chromosomal instability and *KRAS* mutation, whereas sessile serrated adenomas that lack dysplasia can spawn CRCs with microsatellite instability (MSI-hi), *BRAF* mutation, and abundant CpG island methylation.^{5,6} About 8% of sporadic CRCs originate in such lesions, retain a serrated epithelium with characteristic nuclear morphology, and carry a relatively poor prognosis.

Although cancer progression has both genetic (somatic mutations) and epigenetic (unrelated to altered DNA sequence) underpinnings, we presently know more about the former than the latter. Alterations in several classes of genes drive tumors: oncogenes; tumor suppressors, including genes that repair damaged DNA; and those that help control other genes (epigenetic modifiers). Selected mutations appear at high frequencies in different tumor types and stages, allowing for the assignment of typical sequences (Fig. 56.1), although mutational order can vary and most tumors do not carry every alteration. These mutations support the idea of cancer as a multifaceted disease that breaches natural checks on cell survival, growth, and invasion.⁷ Few specific mutations correlate strongly

with particular histologic features or patient survival and most affect multiple cellular functions. Particular genotypes do, however, define CRC subtypes and response to certain therapies. MSI-hi tumors typically arise in the ascending colon and carry a good prognosis; adjuvant 5-fluorouracil provides little benefit in stage II cases of this variety. *KRAS* or *BRAF* mutations, together accounting for about half of all cases, limit response to epidermal growth factor receptor (EGFR) antibodies^{8,9} and are contraindications for this treatment. The prognostic and predictive value of other molecular features will become clearer as new therapies enter the clinic. Meanwhile, specific mutations reveal normal controls on colonic cells, possibly guiding future prevention strategies and key signaling pathways for rational drug development.

Global Events in Colorectal Cancer

CRCs acquire genetic instability in stereotypic ways that favor the accumulation of hundreds to thousands of somatic aberrations (see Fig. 56.1). About 80% of tumors display widespread chromosomal gains, losses, and translocations—phenomena that lead to gene amplifications, rearrangements, and deletions.¹⁰ These tumors carry, on average, below 100 somatic nonsynonymous point mutations. Chromosomal segregation defects may account for chromosomal instability (CIN), as the segregation factor *Bub1* illustrates in mice,¹¹ but few specific gene defects are implicated confidently. Beyond weak associations with structural changes on chromosomes 8 and 18,¹² specific cytogenetic features barely influence disease patterns or patient outcomes.

About 15% of CRCs appear globally euploid but carry thousands of point mutations and small deletions or insertions near nucleotide repeat tracts—the defect designated as MSI-hi.¹³ Features and the molecular determinants of disease progression in MSI⁺ adenomas differ from those associated with CIN; for example, *BRAF V600E* mutations are more common in MSI⁺ precursor adenomas than in other types.¹⁴ Because hypermutability, whether associated with CIN or MSI, results in many changes that are inconsequential or even detrimental to tumors, the mere presence of a mutation does not signify a pathogenic role. Therefore, two features are used to distinguish *driver* from *passenger* mutations: appearance in a high fraction of tumor specimens, and ideally, the experimental demonstration of its contribution to a malignant property.

Epigenetic mechanisms may be as significant as mutations in cancer but are less well understood. Various covalent histone modifications and methylation of cytosine residues in DNA represent prominent modes of gene regulation,¹⁵ the latter being far better characterized in CRCs than the former. 5'-CpG-3' dinucleotide pairs are particular targets for methylation in localized areas of high CpG content in promoters, where methylation silences adjacent genes. CRCs show 8% to 15% lower total DNA methylation than normal tissue,¹⁶ even in colorectal adenomas.¹⁷ Reduced pericentromeric methylation might decrease the fidelity of chromosomal segregation and altered methylation or loss of imprinting at the *IGF2* locus increase CRC risk,¹⁸ suggesting broad effects of global hypomethylation on cell growth. However,

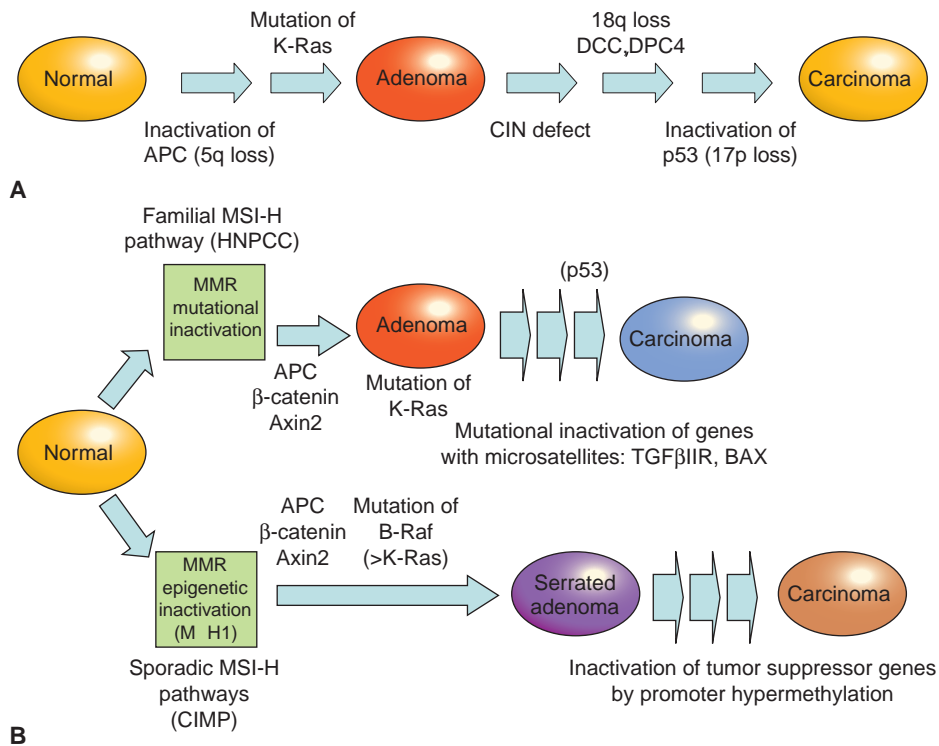

Figure 56.1 Genetic pathways to colorectal carcinoma. All colorectal cancers (CRCs) arise within benign adenomatous precursors, fueled by mutations that serially enhance malignant behavior. Mutations that activate the Wnt signaling pathway seem to be necessary initiating events, after which two possible courses contribute to the accumulation of additional mutations. **(A)** Chromosomal instability is a feature of up to 80% of CRCs and is commonly associated with activating KRAS point mutations and loss of regions that encompass *P53* and other tumor suppressors on 18q and 17p, often but not necessarily in that order. **(B)** About 20% of CRCs are euploid but defective in DNA mismatch repair (MMR), resulting in high microsatellite instability (MSI-hi). MMR defects may develop sporadically, associated with CpG island methylation (CIMP), or as a result of familial predisposition in hereditary nonpolyposis colorectal cancer (HNPCC). Mutations accumulate in the *KRAS* or *BRAF* oncogenes, *p53* tumor suppressor, and in microsatellite-containing genes vulnerable to MMR defects, such as *TGFβIIIR*. Epigenetic inactivation of the MMR gene *MLH1* and activating *BRAF* point mutations are especially common in serrated adenomas, which progress, in part, through the silencing of tumor suppressor genes by promoter hypermethylation. Progression from adenoma to CRC takes years to decades, a process that accelerates in the presence of MMR defects. CIN, chromosomal instability.

its precise significance is unclear because some animals show increased tumor susceptibility with global hypomethylation,¹⁹ whereas *Apc*^{Min} mice lacking or overexpressing the de novo DNA methyltransferase DNMT3B show reduced or accelerated progression of small adenomas, respectively.^{20,21}

Against a backdrop of genomewide hypomethylation, a distinct subset of CRCs shows coordinate hypermethylation of many CpG-rich promoters, conferring the CpG island methylator phenotype (CIMP), with transcriptional attenuation of tumor suppressor genes such as *HIC1* and Wnt-inhibiting *SFRPs*.^{22,23} Whole-genome methylation analyses have confirmed the existence of this once controversial entity²⁴ and features that distinguish it from *KRAS*-mutant CIN disease—origin in sessile serrated adenomas; strong association with *BRAF*-mutant, right-sided MSI-hi tumors with *MLH1* gene methylation;²⁵ and distinctive gene expression patterns.²⁶

Although the features cited previously, especially MMR and CIMP, overlap to some degree, CRCs seem to fall into three general categories: (1) traditional, (2) alternative, and (3) serrated, which are characterized by CIN, DNA mismatch repair, and CIMP, respectively (see Fig. 56.1). The Cancer Genome Atlas (TCGA) Network classified CRCs into nonhypermutated (generally CIN+) and hypermutated (encompassing MMR and CIMP) categories.²⁶ Other variations on the classical adenoma–carcinoma sequence are also recognized. A 10-fold elevated risk of CRC in patients with long-standing ulcerative colitis (UC)²⁷ likely reflects

heightened mutation in a setting of ongoing mucosal injury and repair. UC-associated CRCs often arise within flat adenomatous plaques and nonadenomatous areas of dysplasia. Compared to sporadic cases, *TP53* mutations occur earlier in the cancer sequence,²⁸ *APC* inactivation is less frequent, and methylation of the *p16INK4a* tumor suppressor gene is more common.²⁹

INHERITED SYNDROMES OF INCREASED CANCER RISK HIGHLIGHT EARLY EVENTS AND CRITICAL PATHWAYS IN COLORECTAL TUMORIGENESIS

Two uncommon but highly penetrant Mendelian syndromes, familial adenomatous polyposis (FAP) and hereditary nonpolyposis colorectal cancer (HNPCC), together account for almost 5% of cases. *MYH*-associated polyposis (MAP), polymerase proofreading-associated polyposis (PPAP), familial juvenile polyposis (FJP), Peutz-Jeghers syndrome (PJS), and Cowden disease, each occurring in fewer than 1 in 200,000 births, also elevate the risk of CRCs (Table 56.1). Knowledge about the genes responsible for these inherited disorders allows for accurate molecular diagnosis, risk assessment, and targeted prevention in affected families. It also profoundly informs understanding of the considerably larger proportion of sporadic cases.

TABLE 56.1

Genetics of Inherited Colorectal Tumor Syndromes

Syndrome	Features Commonly Seen in Affected Individuals	Gene Defect
<i>Syndromes with Adenomatous Polyps</i>		
Familial adenomatous polyposis (FAP) – Gardner syndrome – Turcot syndrome	Multiple adenomas (>100) and colorectal carcinomas; duodenal polyps and carcinomas; gastric fundus polyps; congenital hypertrophy of retinal epithelium Same as FAP, with desmoid tumors and mandibular osteomas Polyposis and CRC with brain tumors (medulloblastoma, glioblastoma)	APC (>90%) APC APC, MLH1
Attenuated adenomatous polyposis coli (AAPC)	Less than 100 polyps, although marked variation in polyp number (from ~5 to >1,000 polyps) seen in mutation carriers within a single family	APC (5' mutations)
Hereditary nonpolyposis colorectal cancer (HNPCC)	CRC with modest polyposis; high risk of endometrial cancer; some risk of ovarian, gastric, urothelial, hepatobiliary, and brain cancers	MSH2, MLH1, MSH6 (together >90%), PMS2 (about 5%)
MYH-associated polyposis (MAP)	Multiple gastrointestinal polyps, autosomal recessive	MYH
Polymerase proofreading-associated polyposis (PPAP)	Large adenomas, early-onset CRC, elevated risk of endometrial cancer only	POLE or POLD1
<i>Syndromes with Atypical Polyps</i>		
Peutz-Jeghers syndrome (PJS)	Hamartomatous polyps throughout the gastrointestinal (GI) tract; mucocutaneous pigmentation; estimated 9- to 13-fold increased risk of GI and non-GI cancers	STK11 (30%–70%)
Cowden disease	Multiple hamartomas involving breast, thyroid, skin, brain, and GI tract; increased risk of breast, uterus, thyroid, and some GI cancers	PTEN (85%)
Juvenile polyposis syndrome	Multiple hamartomas in youth, predominantly in colon and stomach; variable increase in colorectal and stomach cancer risk; facial changes	BMPR1A (25%), SMAD4 (15%), ENG
Hereditary mixed polyposis (HMPS)	Polyps of highly heterogeneous form and size, a few of which progress to CRC; confined to rare Ashkenazi Jewish kindreds; only CRC risk is elevated	GREM1 (imputed)

Familial Adenomatous Polyposis and the Central Importance of Wnt Signaling

FAP is an autosomal-dominant monogenic disorder that underlies about 0.5% of all CRCs. Individuals develop hundreds to thousands of colonic polyps by their early 20s, and the lifetime risk of CRC approaches 100% at a median age of 39. Extraintestinal manifestations include (1) duodenal and gastric adenomas; (2) congenital hypertrophy of the retinal pigmented epithelium; (3) osteomas and mesenteric desmoid tumors in the Gardner syndrome variant³⁰; (4) brain tumors in the Turcot syndrome variant³¹; and rarely, (5) cutaneous cysts, thyroid tumors, or adrenal adenomas. Although most of these extraintestinal features are benign, rare patients develop hepatoblastoma or thyroid cancer. Reflecting similar homeostatic mechanisms in the small and large bowel epithelia, a 5% to 10% risk of periampullary adenocarcinoma mandates endoscopic monitoring of the duodenum after prophylactic colectomy.³²

The gene responsible for FAP, *adenomatous polyposis coli* (APC), encodes a 300 kDa protein. Germ-line mutations occur throughout the locus, clustering in the 5' half and exon 15,³³ mostly introducing premature truncations. A few mutations correlate with phenotypic severity or specific extraintestinal manifestations, but identical mutations can produce different features. Mutations clustered in the extreme 5' or 3' ends of APC exons lead to the variant attenuated APC, with few polyps or CRCs developing late in life.³⁴ The *I1307K* allele, present in Ashkenazi Jews,

barely doubles the lifetime risk of CRC over the background and does not affect APC protein function but replaces an (A)₃T(A)₄ coding sequence with an (A)₈ tract that is occasionally targeted for nearby truncating mutations.³⁵ The identification of specific APC mutations in probands allows for a reliable testing of family members. Minimal recommendations for carriers include screening colonoscopy annually after age 10, gastroduodenoscopy after age 25, and treatment with nonsteroidal anti-inflammatory drugs to reduce CRC risk.³⁶ A prophylactic colectomy is highly recommended, with continued vigilance over the rectal stump and other at-risk tissues.

The larger significance of the APC gene derives from its somatic inactivation in about 80% of sporadic CRCs and adenomas,³⁷ including tiny polyps without dysplasia. APC inactivation is a rate-limiting step in the development of most polyps, and knowledge of its cellular functions supports this gatekeeper role. Attending to the tumor suppressor function, CRCs that arise sporadically or in FAP show loss of heterozygosity and biallelic APC inactivation, with one copy usually lost by deletion. Because APC encodes several functional domains, truncated mutant proteins might interfere with various cellular activities. Disruption of its role in chromosome segregation might, for example, contribute to CIN.³⁸ However, attention on APC rightly centers on its control of the Wnt signaling pathway. About half the sporadic CRCs with intact APC function carry activating point mutations in *CTNNB1*,^{39,40} which encodes β -catenin, a transcriptional effector of Wnt signaling; many of the rest carry fusions of genes that

encode R-spondin cofactors.⁴¹ Moreover, acute APC loss in mice produces intestinal defects identical to those observed upon Wnt pathway activation.⁴² APC mutations are uncommon in sporadic cancers outside the intestine.

Wnts are secreted glycoprotein morphogens with diverse developmental and homeostatic functions, and, especially in the intestine, their role is intimately tied to that of R-spondins.^{43,44} In the absence of Wnt ligands, cells use a complex containing APC, AXIN2, and other cytosolic proteins to promote casein kinase I- and glycogen synthase kinase (GSK)-3 β -mediated phosphorylation of conserved serine and threonine residues at the N-terminus of β -catenin; this phosphorylation targets β -catenin for ubiquitin-mediated proteasomal degradation. The binding of Wnt ligands to a surface complex containing a FRIZZLED protein and the obligate coreceptor LRP5/6 inhibits the APC-AXIN2 destruction complex and stabilizes a pool of cytosolic β -catenin (Fig. 56.2), distinct from the abundant cellular stores that attach to E-cadherin on the inner cell surface. Accumulated β -catenin translocates to the cell nucleus, where it coactivates genes bound by sequence-specific transcription factors of the T-cell factor (TCF) family. Of the four proteins in this family, TCF4 is especially important in normal bowel epithelium and CRCs^{39,45} and nuclear β -catenin is necessary to activate target genes.⁴⁶

Figure 56.2 Outline of Wnt signaling, the key driver pathway in colorectal cancer. Members of the Wnt family of glycoprotein morphogens bind the cell surface coreceptors Frizzled and LRP5/6. In the absence of Wnt binding, normal cells use a complex containing APC, Axin, and other cytoplasmic proteins to promote GSK-3 β -mediated phosphorylation of the β -catenin N-terminus, which targets β -catenin for proteasomal degradation (from Clevers H. Wnt/ β -catenin signaling in development and disease. *Cell* 2006;127:469). Binding of a Wnt ligand to Frizzled and its obligate coreceptor LRP5/6 antagonizes the APC/Axin destruction complex, stabilizing β -catenin (CTNNB1), which moves into the nucleus and coactivates genes through T-cell factor/lymphoid enhancer factor (TCF/LEF) transcription factors. Either of the two principal gatekeeper events in colorectal cancer, inactivating APC or activating CTNNB1 mutations, results in constitutive, Wnt-independent stabilization of β -catenin and unregulated activation of the cognate transcriptional program. Wnt signaling in the intestine is normally confined to crypt progenitors, and its aberrant activation by APC or CTNNB1 mutations confers a permanent cryptlike state that favors cell replication.

CTNNB1 mutations in CRC invariably target residues for N-terminal phosphorylation and the mutant protein hence, resists degradation. Thus, both alternative gatekeeper lesions in CRC, inactivating APC or activating CTNNB1 mutations, result in constitutive, Wnt ligand-independent stabilization of β -catenin. R-SPONDIN genes are translocated in up to 10% of cases, all with wild-type APC and CTNNB1,⁴¹ and the gene fusions are probably pathogenic because they potentiate Wnt signaling. TCF4 (also known as TCF7L2) mutations are surprisingly common,²⁶ but their roles and effects are unclear, as is the functional significance of rare AXIN2 mutations in MSI⁺ cases⁴⁷ and of TCF3 or TCF4 gene fusions in microsatellite stability (MSS) cases.⁴⁸

Normal intestinal crypt stem and progenitor cells require Wnt signaling to proliferate, and APC or CTNNB1 mutation-induced loss of this ligand dependence liberates cells from a potent regulatory restraint. Accordingly, the Wnt-dependent transcriptional program in CRC cell lines overlaps significantly with that in intestinal crypts.⁴⁹ Cycling crypt base cells that express the surface marker LGR5 are especially vulnerable to Wnt-induced transformation in mice, suggesting that CRC arises from stem cells and not from mature descendants.⁵⁰ Laboratory evidence suggests that even advanced CRCs remain dependent on constitutive Wnt pathway activity.⁴⁹ The TCF4- β -catenin complex controls hundreds of candidate genes,^{49,51} but the individual significance of most target genes is unclear. *Apc* mutant mice lacking CD44 and selected other Wnt-pathway targets develop fewer adenomas,⁵² but MYC seems especially vital because its absence in mouse intestines completely abrogates effects of acute APC loss.^{53,54}

Hereditary Nonpolyposis Colorectal Cancer and the Role of DNA Mismatch Repair

HNPCC, or Lynch syndrome, an autosomal-dominant disorder that confers about 70% lifetime risk of developing CRCs, usually before age 50, is estimated to account for 2% to 4% of all cases. Affected individuals do not lack colonic polyps (nearly all CRCs, syndromic or sporadic, arise within benign precursors), but develop many fewer polyps than patients with FAP, a condition that must be excluded to satisfy diagnostic criteria for HNPCC (Table 56.2).⁵⁵ Cancers tend to develop in the ascending colon and patients are also predisposed to develop tumors of the endometrium (35% to 50% lifetime risk), ovary and upper urothelium (7% to 8% risk), stomach, small intestine, biliary tract, and brain—a spectrum reflected in the revised Amsterdam II criteria (see Table 56.2).⁵⁶ Cancers in HNPCC show pronounced variation in the lengths of microsatellite DNA sequences, and MSI at two or more among a panel of five mono- and dinucleotide tracts (BAT26, BAT25, D5S346, D2S123, and D17S250) confers the MSI-hi designation. CRCs harboring CIN represent a distinct class and show MSS or, in a small fraction, instability of unclear significance at just one of the five test regions (MSI-lo).

HNPCC results from germ-line mutations in any of several genes that enable DNA mismatch repair (MMR), a proofreading process that corrects base-pair mismatches and short insertions and deletions in the normal course of DNA replication. MMR in mammalian cells is mediated by homologs of bacterial and yeast repair proteins, MutS homologs (MSH) 1 through 6, MutL homologs (MLH) 1 through 3, PMS1, and PMS2. Both MLH1 and PMS2 are recruited to sites of DNA mismatch as a MutL α complex and in turn recruit MSH2-MSH6 (MutS β) or MSH2-MSH3 (MutS β) heterodimers to sites of 1-bp or 2- to 4-bp errors, respectively. These proteins efficiently excise the strand that carries the mismatch and resynthesize and ligate the repaired DNA. Germ-line mutations in MSH2, MLH1, MSH6, and PMS2 together explain about 95% of kindreds,⁵⁷⁻⁵⁹ including a subset with germ-line loss of the stop codon of TACSTD1, which results in silencing of its 3' neighbor MSH2 by hypermethylation.^{60,61}

TABLE 56.2

Criteria for Clinical Diagnosis of Hereditary Nonpolyposis Colorectal Cancer

A. Revised Amsterdam Criteria (Clinical Diagnosis)
1. Three or more family members with histologically verified HNPCC-related cancers, one of whom is a first-degree relative of the other two
2. Two successive affected generations
3. One or more of the HNPCC-related cancers (see C, which follows) diagnosed before age 50
4. Exclusion of familial adenomatous polyposis (FAP)
B. Revised Bethesda Guidelines (Criteria to Prompt Microsatellite Instability Testing of Tumors)
1. Diagnosis of CRC before age 50
2. Synchronous or metachronous presence of CRC or other HNPCC-associated cancer
3. CRC diagnosed before age 60 with histopathologic features associated with MSI-hi
4. CRC in at least one first-degree relative with an HNPCC-related tumor, with one of the cancers diagnosed before age 50
5. CRC in two or more first-degree relatives with HNPCC-related tumors, regardless of age
C. Spectrum of Sites for HNPCC-related Cancers
Colon and rectum, endometrium, stomach, ovary, pancreas, ureter and renal pelvis, biliary tract, small intestine, brain, sebaceous gland adenomas, and keratoacanthomas

MSI-hi colon cancers typically show exophytic growth, lymphoid infiltrates, mucinous signet-ring differentiation, and a medullary growth pattern; Bethesda guidelines (see Table 56.2) combine clinical and phenotypic features to facilitate a diagnosis of HNPCC.⁶² When these criteria are met, tumor DNA should be tested either for MSI in a simple, polymerase chain reaction (PCR)-based assay or by immunohistochemistry for the absence of the commonly implicated MLH1, MSH2, and MSH6 proteins.⁶³ Because Bethesda guidelines might miss up to a quarter of cases, experts now recommend testing all colon cancers arising in patients under 70 years.^{64,65} Coupled with thorough personal and family histories, positive results should prompt DNA testing for MLH1, MSH2, MSH6, or PMS2 mutations.⁶⁶ The identification of mutant alleles and carriers allows for the targeting of cost-effective screening and interventions that are proven to reduce mortality⁶⁵ (e.g., preventive colonoscopy screening every 1 to 2 years, starting around 30 years of age; family counseling; aspirin therapy). Carriers should consider prophylactic subtotal colectomy, hysterectomy, and oophorectomy; females should at least have an annual endometrial evaluation soon after age 30.

In incipient cancers, random events first disrupt function of the wild-type allele of a mutant MMR gene and the resulting *mutator phenotype* promotes DNA replication errors at rates 10^2 to 10^3 times higher than the background.^{13,57} Consequently, adenomas progress into carcinomas over 3 to 5 years instead of 2 or more decades.⁶⁷ Paradoxically, the prognosis for patients with MSI-hi CRCs is better than for those with sporadic MSS disease, perhaps because many resulting somatic mutations place tumors at a disadvantage. Both of the most commonly inactivated genes, ACVR2A and TGFBR2, encode receptors for specific ligands of the transforming growth factor beta (TGF- β) family and contain vulnerable mononucleotide tracts in their coding sequences.^{26,68} TGF- β inhibits the proliferation of intestinal epithelial cells, and biallelic TGFBR2 inactivation is detected in over 90% of MSI-hi and 15% of MSS, sporadic CRCs.⁶⁹ Other genes mutated in familial MSI-hi colon tumors encode the proapoptotic genes

CASP5 and BAX⁷⁰; transcription factor genes, including TCF4⁷¹; and the epidermal growth factor receptor (EGFR)⁷²; but KRAS and, especially, BRAF mutations are rare. CRC pathogenesis requires deregulated APC- β -catenin gatekeeper function irrespective of MMR status.⁷³

MSI-hi is observed in 12% to 15% of sporadic cases of CRC,⁷⁴ often in older patients with early-stage disease. Such tumors seem to arise from sessile serrated adenomas in the ascending colon and do not reflect unrecognized germ-line mutation or somatic disruption of a known MMR gene.⁷⁵ Rather, most but not all cases reflect MLH1 gene inactivation by biallelic promoter hypermethylation and show activating BRAF mutations and CIMP.⁷⁶⁻⁷⁸

MYH-Associated Polyposis and Polymerase Proofreading-Associated Polyposis

Germ-line mutations in MYH, a homolog of the *Escherichia coli* base excision-repair gene MutY cause MAP, a recessively inherited syndrome of multiple adenomas and CRC.⁷⁹ CRC develops later in life than in FAP, polyp numbers vary widely, and extracolonic tumors are less frequent than in HNPCC (see Table 56.1). Because MYH is a DNA glycosylase that helps repair oxidative DNA damage, tumors are not associated with MSI but with somatic G:C to T:A mutations, including in the APC gene. Two alleles, Y165C and G382D, account for most cases, and CRCs develop in homozygotes or compound heterozygotes, with no risk elevation in monoallelic carriers.⁸⁰ Surveillance recommendations are the same as in HNPCC.

Rare kindreds with a dominantly inherited high risk of CRC carry particular germ-line defects in POLE and POLD1, which encode the proofreading exonuclease activities of the leading- and lagging-strand DNA polymerases ϵ and δ , respectively.⁸¹ Clinical findings of large adenomas and early-onset CRCs resemble those in HNPCC or MAP, including elevated endometrial cancer risk in women with mutant POLD1. Tumors carry thousands of mutations, but stable microsatellite tracts reveal a third familial *mutator* mechanism in CRCs. Hypermutation in the absence of MSI accounts for about 3% of sporadic CRCs, nearly all of which have a somatic POLE exonuclease domain and also APC mutations.²⁶ POLE and POLD1 are nonclassical tumor suppressors because, instead of deletion or truncation, specific missense mutations affect proofreading function, and the wild-type allele is usually retained. Until further characterization of PPAP leads to formal surveillance recommendations, it is prudent to adopt those developed for HNPCC.

Familial Juvenile Polyposis and the Peutz-Jeghers, Hereditary Mixed Polyposis, and Cowden Syndromes

Patients with FJP develop premalignant hamartomatous polyps in the stomach or the small or large intestine by adolescence^{82,83} and may give a revealing family history, although a significant minority represent the first case in their families. Germ-line mutations in genes encoding the bone morphogenetic protein (BMP) receptor BMPRIA, the accessory TGF- β receptor endoglin, ENG, or the SMAD4 signal transducer emphasize the role of TGF- β signaling in disease pathogenesis (see Table 56.1).^{84,85} Indeed, sporadic CRCs are often insensitive to the growth inhibitory effects of TGF- β and loss of BMP function in mice expands stem and progenitor cells, leading to polyposis or ectopic crypts.⁸⁶⁻⁸⁸ Not all patients carry these mutations, indicating that additional genes remain undiscovered. Notably, a conditional *Smad4* deletion from mouse intestinal cells does not affect growth, whereas selective loss in T lymphocytes causes intestinal mucosal thickening and polyyps.⁸⁹ These findings confound simple interpretations of TGF- β function and implicate stromal inflammation in intestinal tumorigenesis.

Patients with PJS also develop benign tumors that contain differentiated but disorganized cells (hamartomas), mainly in the small intestine but also in the colon or stomach, sometimes leading to hemorrhage or intussusception. PJS shows autosomal-dominant inheritance and is associated with macular lesions on the skin and buccal mucosa; bladder and bronchial polyps; and a propensity to develop a range of cancers, including those of the lung, breast, and female reproductive organs (see Table 56.1). The lifetime risk for all cancers exceeds 90%, the incidence of small intestine, stomach, and pancreas cancers is 50 to 500 times higher than the general population, and CRC risk is elevated nearly 100-fold.⁹⁰ *Serine-threonine kinase 11* (*STK11*, also known as *LKB1*), the implicated tumor suppressor gene,⁹¹ acts at the nexus of diverse cellular pathways and functions. Its principal activity, exerted through the adenosine monophosphate (AMP)-activated protein kinase AMPK, seems to be in linking nutrient and energy utilization to controls over cellular structure, particularly cell polarity.⁹² *STK11* also modulates the Rheb-GDP:Rheb-GTP cycle and downstream activities of the tuberous sclerosis gene *TSC2* and the mammalian target of rapamycin (mTOR),⁹³ key regulators of protein synthesis and cell growth. The roles of *STK11* in cell polarity and metabolism are busy areas of research, likely to hold vital clues into CRC pathogenesis and rational therapy.

Confined to rare Ashkenazi Jewish kindreds descended from a single founder, patients with HMPS develop polyps of several diverse morphologies and CRCs but no other cancers.⁹⁴ A 40-kb duplication upstream of *GREM1* seems to activate a distant enhancer of this BMP antagonist gene, driving ectopic and high expression in the colonic epithelium.⁹⁵ The resulting increased crypt cell turnover likely accelerates the accumulation of oncogenic mutations. *GREM1* is also the locus of a CRC risk allele identified at 15q13.3 in a GWA study.⁹⁶

Cowden disease encompasses diverse mucosal lesions, specific cutaneous lesions (facial trichilemmomas and acral verrucous papules), and breast fibroadenomas, neurofibromas, lipomas, and meningiomas.⁹⁷ The syndrome results from germ-line mutations in *PTEN*, a tumor suppressor gene encoding the phosphatase and tensin homolog deleted on chromosome 10,⁹⁸ and the second most frequently mutated gene in cancers after *TP53*. The lipid phosphatase *PTEN* dephosphorylates key phosphoinositide (PI) signaling molecules⁹⁹ and accordingly regulates intracellular growth signaling negatively through PI-3 kinase and its downstream effectors AKT and mTOR. The CRC risk in Cowden syndrome is modest, and *PTEN* mutations are rare in sporadic cases, but protein immunostaining is lost in about 40% of CRCs, often as a result of promoter hypermethylation,¹⁰⁰ thus highlighting its tumor suppressor role.

Significance of Inherited Syndromes of Elevated Colorectal Cancer Risk

Following a clinical diagnosis of the previous Mendelian syndromes, patients and family members should be tested for pertinent germ-line mutations, receive genetic counseling, and enter programs for cancer prevention and screening. The corresponding molecular defects profoundly inform an understanding of sporadic CRCs, in particular, revealing the seminal role of Wnt signaling and early, rate-limiting effects of *APC* inactivation or *CTNNB1* activation. Similarly, *STK11* and *PTEN* loss in inherited and sporadic CRCs shed light on crucial molecular pathways, whereas HNPCC and PPAP help classify the disease and reveal the significance of features such as MSI, which is present in 12% to 15% of sporadic cases. Even in the absence of a recognized predisposition syndrome, individuals with a history of CRC in a first-degree relative are up to 4 times more likely to develop CRC than those without a family history. Specific environmental factors that compound the risk of developing CRCs are complex and insufficiently characterized, but include obesity, excessive consumption of red meat, physical inactivity, and vitamin D deficiency.¹⁰¹ Because many of

these factors converge on insulin signaling, some experts propose that insulin and insulinlike growth factors play a seminal role in CRCs.¹⁰² However, three of every four CRCs arise in individuals lacking a well-defined risk factor, and it is unknown to what extent particular genotypes confer sensitivity to environmental variables.

The cancer spectrum in HNPCC or PPAP and the particular predilection for CRC remain unexplained. Colonic, endometrial, and selected other epithelia may be especially sensitive to the kind of mutations that occur in the setting of defective DNA mismatch and base-excision repair, loss of wild-type tumor suppressor alleles may occur more readily in these tissues, or they may lack repair safeguards that protect other cell types.

Insights from Genomewide Association Studies

The quarter or more of sporadic CRC cases with a familial component^{103,104} probably have diverse molecular etiologies, with low risk conferred by some common genetic variants and interaction of individual risk alleles with other genes and with environmental factors. Large multinational GWA studies have interrogated thousands of genomes and, to date, have uncovered statistical association of CRC risk with at least 20 distinct loci, including those linked to single nucleotide polymorphisms (SNPs) rs6983267 at 8q24.21, rs4939827 on 18q21, and rs3802842 at 11q23 (Table 56.3). The frequency of risk alleles ranges from less than 10% to half or more of the human population and each one elevates CRC risk no more than 7% to 25% above the background in persons with the nonrisk allele.^{105,106} Even if homozygosity at some loci and additive effects compound this risk, allele frequencies are such that the cumulative risk rises no more than 50% to 250% over the background. As a result, the total effect of all identified risk variants explains, at most, 5% to 7% of cases with a family history; it is not presently feasible to predict an individual's precise risk or modify screening recommendations on the basis of known genotypes. Nevertheless, the identification of risk loci is a crucial advance for an eventually thorough understanding of disease determinants.

The specific causal significance of most of these DNA sequence variants is unclear and many localize far from coding genes, with growing evidence that they correspond to regulatory regions for control of nearby genes. This implies that an altered expression of the linked genes either transforms normal colonocytes at low frequency or, more likely, influences the oncogenic potential of other events. Particularly strong association occurs with the SNP rs6983267 at 8q24.21, which lies in a gene desert near low-risk susceptibility alleles for breast and prostate cancers. Molecular studies indicate that each culpable region acts as a tissue-specific enhancer controlling the nearest gene, *CMYC*,¹⁰⁷⁻¹⁰⁹ thereby modulating disease risk.¹¹⁰ Attesting to the role of TGF- β signaling in colonic epithelial homeostasis, risk alleles on chromosomes 18q21 and 14q22 are linked to *SMAD7* and *BMP4*, respectively.^{111,112} Some genes near risk variants are not expressed in the colonic mucosa, suggesting a role for extraepithelial genetic effects from stromal or immune cells. In summary, at least 20 common polymorphisms elevate CRC risk modestly and with sufficiently low penetrance that effect detection requires large population-based analyses. The pathophysiologic functions of these loci will likely inform future prevention and screening strategies and help determine how risk alleles interact with environmental factors.

ONCOGENE AND TUMOR SUPPRESSOR GENE MUTATIONS IN COLORECTAL CANCER PROGRESSION

Building on the foundation of lost gatekeeper functions in Wnt signaling, somatic mutations in oncogenes and tumor suppressor

TABLE 56.3

genes cumulatively confer malignant properties. The particular spectrum of recurring mutations in CRC provides a framework to decipher the oncogenic signaling circuits and develop rationally targeted drugs (Table 56.4). The high collective frequency of recurrent *KRAS*, *BRAF*, and *PIK3CA* mutations places EGFR and downstream extracellular signal-regulated kinase (ERK, also known as mitogen-activated protein kinase [MAPK]) signaling at the center of research and therapeutic efforts.

The *KRAS*, *BRAF*, and *PIK3CA* Oncogenes

Ras-family G-proteins transduce growth factor signals and are aberrantly activated in a wide variety of cancers. *KRAS* is mutated in about 40% of CRCs¹¹³ and *NRAS* in another 5% to 8% of cases. Mutations in both genes cluster in codons 12 or 13, and less frequently at codon 61. *KRAS* mutations appear even in lesions of low malignant potential, such as aberrant crypt foci lacking dysplasia,¹¹⁴ and certainly in small polyps, although their frequency increases with lesion size.¹¹⁵ A *KRAS* mutation is not required to initiate adenomas, but contributes to disease progression when combined with other genetic alterations, and specific interference with mutant *KRAS* in CRC cells and xenografts impedes cell growth.^{116,117} Among the many different growth factor receptor signals that *KRAS* transduces in diverse cells, its activity in the colonic epithelium and CRC is particularly related to EGFR signaling, which is important for two reasons. First, inasmuch as Wnt and EGFR signaling drive normal gut epithelial turnover, CRC appears to subvert tissue-specific homeostatic circuits. Second, because a *KRAS* mutation introduces intracellular defects that lock EGFR signaling in the “on” state, EGFR antibodies are ineffective in this subset of CRCs⁸ and targeted therapies will need to interfere further downstream in the signaling pathway.

Because *KRAS* acts early in transducing signals from EGFR and other receptor tyrosine kinases, *KRAS* mutations can

potentially deregulate several effector pathways for cell survival, proliferation, invasion, and metastasis (Fig. 56.3). Constitutive phosphorylation of ERKs accompanies *KRAS* mutation, reflecting the activation of the ERK/MAPK pathway.¹¹⁸ *KRAS*-mediated growth factor signaling recruits RAF kinases to the plasma membrane and triggers MEK1 and MEK2 kinases to activate ERK1 and ERK2, which in turn phosphorylate proteins that control the G₁-S cell cycle transition, among other substrates.¹¹⁹ Although other, non-*KRAS*-mediated growth factor pathways also activate the MAPK cascade, signaling in CRC is most often deregulated through activating mutations in *KRAS* or *BRAF*. *BRAF* is mutated in about 10% of CRCs, especially those associated with MSI and CIMP.^{120,121} The most common *BRAF* mutation in CRCs, melanoma, and selected other cancers, *V600E*, affects a residue within the activation loop of the kinase domain and constitutively activates kinase function, probably by several hundred-fold and acting as a phosphomimetic.¹²² Like mutant *KRAS*, activated *BRAF* also phosphorylates ERKs, lifting intrinsic restraints on cell growth. Indeed, *KRAS*, *NRAS*, and *BRAF* mutations are mutually exclusive in CRCs,^{26,120} highlighting their actions in a common cellular pathway and reflecting alternative routes to the same end.

Several features of *BRAF*-mutant CRCs are noteworthy. First, the defect confers a worse prognosis than *KRAS* mutations in advanced disease,^{9,123} which indicates distinctive molecular or cellular features. Second, the *BRAF* mutation is a hallmark of non-familial MSI-hi CRC and occurs early in the natural history of sessile serrated adenomas.¹²¹ Third, whereas forced *Kras* activation in the mouse intestine has a modest independent consequence,^{124,125} *BrafV600E* expression rapidly induces persistent generalized hyperplasia with a high penetrance of crypt dysplasia, serrated morphology, and MSI-hi invasive cancers that show Wnt pathway activation.¹²⁶ Fourth, tumors mutant for either *KRAS* or *BRAF* intrinsically resist treatment with EGFR antibodies.^{9,123} Fifth, *BRAFV600E* mutant melanomas initially respond to selective,

TABLE 56.4

Recurrent Somatic Gene Mutations in Human Colorectal Cancers

Gene	Frequency	CRC Class	Known Cellular or Oncogenic Function
<i>Oncogenes</i>			
<i>KRAS</i>	35%–40%	CIN	RTK signaling
<i>PIK3CA</i>	18%–20%	Mostly CIN	RTK signaling
<i>BRAF</i>	7%–15%	MSI-hi, CIMP	RTK signaling
<i>NRAS</i>	9%	CIN	RTK signaling
<i>ERBB3</i>	~8%	CIN	RTK signaling
<i>CTNNB1</i>	~5%	All	Wnt pathway activation
<i>Tumor Suppressor Genes</i>			
<i>APC</i>	85%	All	Wnt pathway inactivation
<i>TP53</i>	50%	CIN predominant	Stress, hypoxia response; DNA replication
<i>SMAD4</i>	10%	CIN	
<i>FBXW7</i>	10%	CIN	
<i>SOX9</i>	5%	CIN	Wnt-dependent ISC function
<i>ACVR2A</i>		MSI-hi	Wnt pathway activity
<i>TGFBR2</i>		MSI-hi	TGF- β signaling
<i>MSH3</i>		MSI-hi	DNA mismatch repair
<i>MSH6</i>		MSI-hi	DNA mismatch repair
<i>POLE</i>		Hypermutated (non-MSI)	DNA polymerase ϵ
<i>Epigenetic Modifier Genes (Roles Are Emerging)</i>			
<i>ARID1A</i>		MSI-hi	Chromatin remodeling
<i>SIN3A</i>			Transcriptional repression
<i>SMARCA5</i>			Chromatin remodeling
<i>NCOR1</i>			Transcriptional repression
<i>JARID2</i>			Histone modification
<i>TET1, 2, 3</i>			DNA demethylation

RTK, receptor tyrosine kinase; ISC, intestinal stem cell.

ATP-competitive BRAF inhibitors such as vemurafenib and take months to manifest secondary resistance,¹²⁷ whereas BRAFV600E mutant CRCs are intrinsically resistant and barely respond to the same agents. This is because BRAF inhibition in CRC quickly induces feedback EGFR signaling through KRAS and CRAF, restoring stimuli for cell replication (melanoma cells hardly express EGFR and therefore avoid this feedback activation).^{128,129} Because BRAF inhibition renders cells newly sensitive to direct antagonism of EGFR, a combined antagonism of BRAF and EGFR signaling may be beneficial.

KRAS signals are transduced not only through ERKs, but also through phosphatidylinositol (PI) 3-kinase (PI3K),^{118,130} which phosphorylates the intracellular lipid PI-4,5-bisphosphate at the three position, triggering a cascade that promotes cell survival and growth.¹³¹ Up to 20% of CRCs carry activating mutations in *PIK3CA*, the gene encoding the catalytic p110 subunit of PI3K. Mutations cluster in exons 9 and 20 and seem to arise late in the adenoma–carcinoma sequence, possibly coincident with invasion¹³²; many fewer CRCs carry related *PIK3R1* mutations. Cellular PI3K activity is countered by the product of the *PTEN* gene, which is inactivated (usually by deletion) in another 10% of cases. Although both PI3K and BRAF act downstream of KRAS, only BRAF and KRAS mutations are mutually exclusive; up to one-fifth of KRAS-mutant CRCs also have *PIK3CA* mutations, implying that these oncogenes are not trivially redundant. One reason could

be that mutant KRAS activates PI3K signaling inefficiently.¹³³ More likely, oncogenic signaling pathways are less strictly linear than is convenient to depict. Indeed, seemingly parallel streams of KRAS signaling through RAF–MEK and PI3K (see Fig. 56.3) interact extensively with one another and both streams feed into the mTOR, which coordinates cell growth with nutrient responses.¹³⁴ Lastly, insulinlike growth factor 2 (IGF2) is overexpressed in at least 15% of CRCs as a result of focal gene amplifications, loss of imprinting, and other mechanisms.²⁶ Overexpression of *IGF2* and its downstream effector *IRS2* is mutually exclusive with *PIK3CA* mutations and *PTEN* deletions, strongly implying that the underlying genetic aberrations represent alternative means to disrupt the same signaling circuit.

MYC, CDK8, and Control of Cell Growth and Metabolism

Although the *MYC* and *CDK8* oncogenes are rarely mutated in CRC, considerable gene amplification is seen in at least 10% of cases, with moderate increases in copy number and expression in up to 25% of cases.^{26,135} Aberrant *MYC* gene regulation likely explains the significant GWA studies risk allele rs6983267 and *MYC* expression is not only a prominent outcome of Wnt signaling,⁴⁹ but may account for the bulk of the tumor effect in *Apc*-mutant

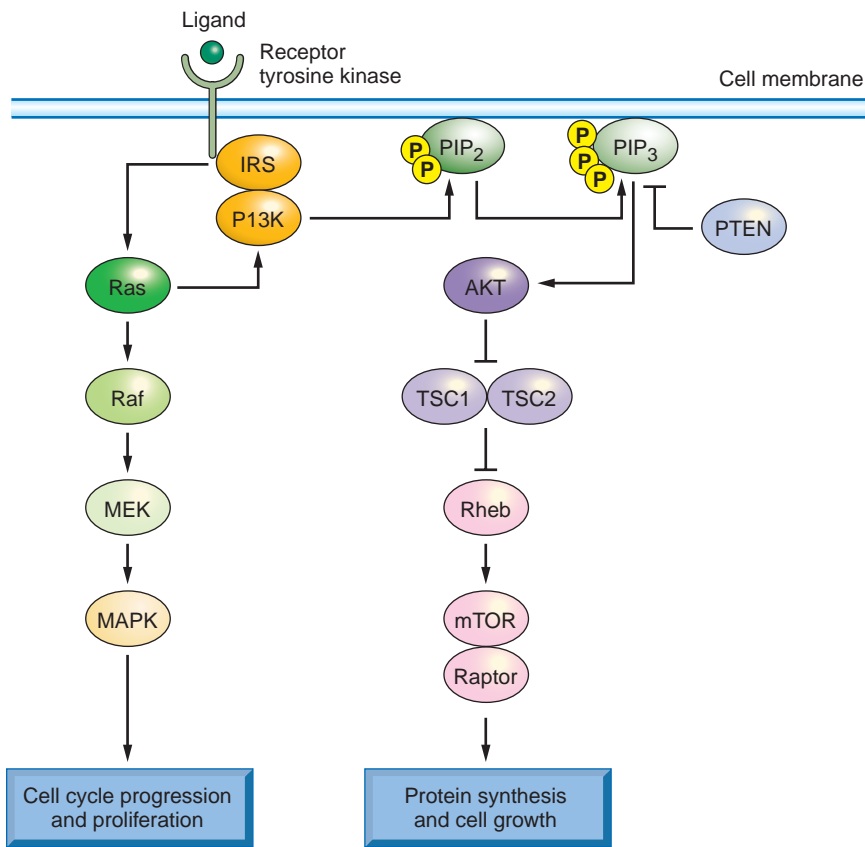

Figure 56.3 Signaling pathways, oncogenic mutations, and therapeutic opportunities in CRC. It is instructive to consider common genetic alterations in CRC in light of a common canonical outline of signaling through receptor tyrosine kinases, among which the EGFR is a prime example. *KRAS*, the oncogene mutated in up to 40% of CRCs, signals receptor activation through RAF proteins (including BRAF, which is mutated in 5% to 8% of CRCs) and phosphatidylinositol 3-kinase (PI3K), whose catalytic PIK3CA subunit is mutated in 15% to 20% of CRCs. These transducers in turn activate the intracellular mitogen-activated protein kinase and AKT or mTOR pathways, respectively. Hence, common mutations confer growth factor independence on cells, resulting in dysregulated proliferation, protein synthesis, and metabolism. They also represent promising targets for therapeutic interference with aberrantly activated signaling cascades.

mouse intestines.⁵⁴ CDK8, a cyclin-dependent kinase component of the Mediator complex, couples transcription factors to the basal transcriptional machinery and hence resembles MYC in regulating thousands of genes, including those necessary for cellular metabolism, proliferation, and self-renewal. CDK8 activity in CRC is particularly associated with β -catenin.¹³⁵ Indeed, although *APC*, *CTNBN1*, and probably *RSPO* mutations kick start colonic adenomas, additional genetic events in CRC potentiate Wnt activity. Disrupting this seminal pathway and/or its downstream effector MYC may therefore be imperative in CRC therapy, but poses formidable challenges, in part because that requires interfering with protein-protein interactions downstream of conventional druggable nodes.¹³⁶

TP53 and Other Tumor Suppressors

The allelic loss of chromosome 17p is observed in three of every four CRCs but <10% of adenomatous polyps.¹¹⁵ The remaining *TP53* allele is inactivated in most tumors with 17p loss of heterozygosity (LOH), most often at codons 175, 245, 248, 273, or 282.¹³⁷ *TP53* mutations, found in half of all CRCs and LOH of 17p thus appear to arise late in the transition from adenoma to carcinoma, possibly facilitating progression. Cells with an intact *TP53* function undergo cell cycle arrest and apoptosis when faced with stress from DNA damage, hypoxia, reduced nutrient access, or aneuploidy. *TP53* loss may allow cells to overcome these barriers to tumor survival and progression, but confers no specific disease features in CRCs.

LOH of chromosome 18q, which is rare in small to midsize adenomas, is observed in >60% of CRCs and nearly all liver metastases from MSS tumors.¹³⁸ This sequence implicates loss of resident genes in disease progression, but 18q LOH does not by itself confer a poor prognosis.¹³⁹ The minimal common region of LOH contains two candidate tumor suppressor genes¹⁴⁰: *SMAD4* (*DPC4*) in about one-third of cases and *DCC* (deleted in

colorectal cancer, a receptor for Netrin axonal guidance proteins) in the rest. *SMAD4/DPC4* and *SMAD2* are positive and negative regulators of TGF- β signaling, respectively, and closely linked on 18q. Somatic *SMAD4* mutations are present in 10% to 15% of CRCs with LOH, and germ-line mutations are noted in some FJP kindreds¹⁴¹; *SMAD2* and *DCC* are rarely mutated in CRC,¹⁴² but *DCC* mRNA and protein are lost in >50% of cases.¹⁴³ Together, these findings suggest a complex, multifactorial basis for the selection of 18q LOH in CRC.

FBXW7 (F-box and WD40 repeat domain containing 7), another gene frequently inactivated in CRCs, encodes a receptor subunit of Skp, Cullin, F-box-containing (SCF)-E3 ubiquitin ligase complexes, which target multiple regulators of cell growth, such as MYC and JUN transcription factors, for degradation. Monoallelic missense mutations tend to cluster in arginine residues within a β -propeller domain that recognizes specific substrates, including NOTCH, JUN, DEK, and TGIF1 in intestinal cells.^{144,145}

THE MUTATIONAL LANDSCAPE OF COLORECTAL CANCER

Early analyses of protein-coding genes in a few CRCs produced average estimates of 81 mutations per tumor and spawned the useful idea that the mutational landscape of CRC contains few mountains (genes such as *APC*, *KRAS*, *TP53*, and *PIK3CA*, with frequent mutations) or hills (less frequent but functional mutations [e.g., *BRAF*^{V600E}]).¹⁴⁶ Although many additional events are individually infrequent and may contribute to neoplasia sporadically or represent *passenger* mutations, they tend to congregate in genes that control cell adhesion, signaling, DNA topology, and the cell cycle.¹⁴⁷ In general, CRCs show a genome-wide bias toward C:G to T:A transitions at 5'-CpG-3' sites and a lower frequency of mutations in 5'-TpC-3' dinucleotides than observed, for example, in breast cancer.¹⁴⁶ Such findings may eventually link specific

environmental factors to characteristic mutational spectra. Moreover, an average of 17 genes are deleted or amplified to 12 or more copies per CRC cell,¹⁴⁸ and the oncogenes *ERBB2*, *MYC*, *KRAS*, *MYB*, *IGF2*, *CCND1*, and *CDK8* are in aggregate amplified or overexpressed in most cases, usually together with neighboring genes. Nearly half the copy number alterations—28 amplifications and 22 deletions, including 15 recurrent changes encompassing <12 genes—identified in one study¹⁴⁹ also appear in other cancers. CRCs thus reflect the perturbation of selected pathways of replicative and tissue homeostasis, some in common with most cancers and others restricted to CRCs.

Detailed data from two genome-scale studies of nearly 300 CRCs and matched normal tissue corroborate these general observations and provide reliable catalogs of genetic alterations.^{26,41} These comprehensive efforts revealed *RSPO* gene fusions and up to 10% incidence of monoallelic missense mutations in *SOX9*, a transcription factor target of Wnt signaling that is highly expressed and active in intestinal crypt stem and progenitor cells.¹⁵⁰ Additionally, MSI-hi tumors showed frequent mutations in the *ARID1A* chromatin remodeling factor gene, which may affect a broad swath of other genes. An updated, partial list of recurrent genetic alterations in CRC (see Table 56.4) indicates that few new mutations fall in genes that appeal to the pharmaceutical industry, such as tyrosine or serine/threonine kinases.

Prognostic and Predictive Value of Molecular Properties and Tumor Genotypes

These specific genetic alterations might confer particular clinical behaviors, prognoses, or drug responses. Mutational, chromosome structural, and gene expression profiles are virtually identical in colonic and rectal adenocarcinomas. Aneuploidy and tetraploidy confer a worse prognosis than MSI-hi status in early-stage disease,¹⁵¹ and the benefits of adjuvant 5-fluorouracil therapy may be restricted to patients with MSS tumors.^{152,153} Because nearly all CRCs have a constitutive Wnt pathway activity, this element alone has limited prognostic value and outcomes seem unaffected by whether *APC* or *CTNNB1* mutations stimulate the pathway. The presence of *KRAS* or *BRAF* mutations and possibly also *PIK3CA* mutation or loss of *PTEN* expression predicts a lack of response to EGFR monoclonal antibodies.^{8,154} These are important observations because they direct treatment decisions and because, unlike leukemias or breast cancer, CRCs had previously resisted subgrouping on the basis of specific gene alterations. For example, mutations in the two most frequently affected oncogenes, *KRAS* or *PIK3CA*, seem not to impact survival in stage III or stage IV disease treated with chemotherapy,^{9,155} although they will likely predict responses to new agents that target MEK or PI3 kinase signaling, respectively. Patients with metastatic *BRAF*-mutant CRC have especially low survival and respond poorly to current chemotherapy regimens, including adjuvant fluoropyrimidines in stage III disease.^{9,156}

AN INTEGRATED MODEL FOR COLORECTAL CANCER INITIATION AND PROGRESSION

Intensive molecular investigation has informed our understanding of CRC for more than 2 decades, with crucial independent contributions from delineation of the adenoma–carcinoma sequence, uncommon familial syndromes, the Wnt–Rspo– β -catenin pathway, and EGFR signaling through the *KRAS*–*BRAF*–ERK and *PIK3CA*–AKT–mTOR pathways. Together with whole-genome analyses of CRC and refined investigation of intestinal crypt biology in animals, a large corpus of knowledge now permits a coherent model of disease initiation and advance.

Animal Models of Colorectal Cancer Genetics

Similar intestinal cell properties and genetics in humans and mice make the laboratory mouse valuable in the investigation of CRCs. The *multiple intestinal neoplasia* (*Min*) strain has a truncating mutation in *Apc* and phenocopies human FAP with respect to intestinal adenomas,¹⁵⁷ although tumors form mainly in the small bowel. *Apc*^{Min} mice are a cornerstone for the genetic analysis of intestinal polyps and deregulated Wnt signaling, but other *Apc* mutants also have value. A *D716* allele increases the number of adenomas, all with loss of the wild-type copy,¹⁵⁸ whereas a larger fraction of *Apc*^{1638N} adenomas appear in the colon¹⁵⁹; *Apc*^{Pirc} rats carry a stop codon at position 1137 and more than half the tumors arise in the colon.¹⁶⁰ Deletion of the N-terminal degradation domain of murine β -catenin also stabilizes the protein and induces widespread intestinal polyposis.¹⁶¹ Expression of activated *Kras* alleles in the intestinal epithelium of otherwise intact mice barely affects cell signaling or proliferation, but similar to human CRCs, expression on *Apc* mutant backgrounds expands progenitor cell numbers and hastens adenoma progression.^{124,125} In contrast, activated *Braf* induces crypt hyperplasia, followed by invasive cancers with deregulated Wnt and ERK signaling.¹²⁶ The inactivation of murine genes for DNA MMR¹⁶² leads to more lymphomas than intestinal tumors, with some mutants showing neither but revealing roles in meiosis; MMR is nevertheless necessary for protecting cells from mutation and malignancy.

Integrated Insights from the Study of Human Colorectal Cancers and Mouse Intestinal Crypts

Animal studies strongly suggest that CRCs originate in resident intestinal epithelial stem cells.⁵⁰ These cells, characterized mainly in the mouse small bowel, replicate frequently and neutral drift ensures that each normal crypt contains a monoclonal population of five to eight functional stem cells.^{163,164} Gatekeeper mutations in *APC* or *CTNNB1* in one such cell induce constitutive Wnt pathway activity; the attendant growth advantage allows this mutant stem cell to dominate that crypt and eventually take hold as a monoclonal population. Notably, the outcome of this stochastic process is not inevitable: Neutral drift permits either wild-type or *APC*-mutant cells to replace each other quite rapidly, but a selective advantage in the latter gives them a demonstrable edge over their wild-type siblings.¹⁶⁵ Once a mutant stem cell clone is established, with no competing wild-type cells remaining in that crypt, it can flourish indefinitely and accumulate mutations as they occur, by chance or by virtue of a hypermutable state, so long as a mutation is not lethal or severely detrimental. Again, the outcome is not inevitable: Few polyps advance into carcinomas and others may even regress. Eventually, various combinations of mutations that co-opt existing signaling circuits confer invasive properties on a fraction of adenomas. Indeed, the bulk of observed mutations represent alternative means to dysregulate the same few pathways—Wnt, EGFR, TGF- β , IGF2, and PI3K—that control normal colonic cell turnover. Therefore, although specific genes, such as *BRAF* and *PIK3CA*, represent obvious targets for molecular therapy, it may be more useful in the long run to consider CRCs with broad respect to the pathways in which commonly mutated genes operate.

SUMMARY

The adenoma–carcinoma sequence represents the overt pathologic manifestation of sequential genetic alterations that promote cell growth, survival, and invasion. Molecular genetic studies have revealed crucial underlying mutations and the contribution of specific defects toward CRC pathogenesis. Colonic adenomas begin

with deregulated Wnt signaling and this pathway's functions in intestinal crypt homeostasis lead us to interpret cancer in relation to pools of normal tissue stem cells. MSI-hi distinguishes CRCs that arise in the setting of HNPCC and about 15% of sporadic cases from the larger fraction of cases with CIN, leading to a molecular classification into at least three disease subgroups with distinctive features, natural histories, and treatment considerations. Somatic mutations associated with tumor progression involve a small

selection of signaling and homeostatic pathways, revealing candidate therapeutic targets. Further work on the biologic functions of inherited and somatic mutations will help design novel, rational, and targeted therapies. Much also remains unknown about how environmental factors impinge on the implicated key pathways to modulate CRC risk and about specific interventions to prevent a cancer whose incidence and lethality in developed countries is second only to lung cancer.

57 Cancer of the Colon

Steven K. Libutti, Leonard B. Saltz, Christopher G. Willett,
and Rebecca A. Levine

INTRODUCTION

A more thorough understanding of the molecular basis for this disease, coupled with the development of new therapeutic approaches, has dramatically altered the way in which patients with colorectal cancer (CRC) are managed. This chapter and the one that follows will provide an up-to-date description of the current state of the science and outline a multidisciplinary approach to the patient with colon or rectal cancer.

EPIDEMIOLOGY

Incidence and Mortality

Globally, nearly 1,200,000 new CRC cases are believed to occur, which accounts for approximately 10% of all incident cancers, and mortality from CRC is estimated at nearly 609,000.¹ In 2010, there were an estimated 141,570 new cases of CRC and 51,370 deaths in the United States.² As such, CRC accounts for nearly 10% of cancer mortality in the United States. Prevalence estimates reveal that in unselected individuals age 50 years or older, there is a 0.5% to 2.0% chance of harboring an invasive CRC, a 1.0% to 1.6% chance of an in situ carcinoma, a 7% to 10% chance of a large (≥ 1 cm) adenoma, and a 25% to 40% chance of an adenoma of any size.³

Age impacts CRC incidence greater than any other demographic factor. To that end, sporadic CRC increases dramatically above the age of 45 to 50 years for all groups. In almost all countries, age-standardized incidence rates are less for women than for men. Although CRC incidence has been steadily decreasing in the United States and Canada, the incidence is rapidly increasing in Japan, Korea, and China.¹ In the United States from 2002 to 2006, the age-standardized incidence rates per 100,000 population were 59.0 for men and 43.6 for women when combined for all races.² Recognizing that decreases in age-standardized CRC incidence and mortality rates are apparent in the United States over the past 10 to 15 years, such trends may be counterbalanced by prolonged longevity.

While the incidence of CRC in the United States has decreased overall, presumably due to aggressive screening of the population over age 50, there has been a dramatic increase in younger patients. A new study using data from the Surveillance Epidemiology and End Results (SEER) program found a rising incidence of CRC over the last 20 years in patients aged 20 to 49. The most pronounced growth was in the age group 40 to 44 where colon and rectal cancer increased 56% and 94%, respectively. Based on these findings and the fact that CRC in younger patients tends to be more advanced, the authors recommend lowering the age for average risk screening by 10 years.^{4,5}

Geographic Variation

The incidence rate for Alaskan Natives exceeds 70 per 100,000,⁶ while that for Gambia and Algeria is < 2 per 100,000.⁷ Generally

speaking, CRC incidence and mortality rates are the greatest in developed Western nations.^{1,7} The reader is referred to the most recent detailed incidence and mortality rates in different countries over time according to gender, ethnicity, and anatomic site as established by the National Cancer Institute on their website.

As mentioned, there appears to be a recent decrease in age-standardized CRC incidence and mortality rates within the United States. From 1999 to 2006, CRC incidence and mortality both decreased.² Furthermore, 5-year survival improved. These trends are apparent regardless of gender, race, or ethnic group, except for Native Americans. Although at an initial glance one might invoke alterations in dietary and lifestyle factors, or the utilization of chemopreventive agents, it is clear that enhanced use of colonoscopy with polypectomy represents a significant reason for the improvements in trends in some areas.⁸

Emigration Patterns in Population Groups

Seminal studies have revealed that migrants from low-incident areas to high-incident areas assume the incidence of the host country within one generation.⁹⁻¹² For example, for Chinese who immigrate to the United States, higher CRC rates have been ascribed to greater meat consumption and diminished physical activity in contrast to controls within their original country.¹⁰ These and other studies underscore the importance of environmental exposure in CRC incidence and provide a platform for attention to dietary and lifestyle modification as preventive measures.

Race and Ethnicity

Although dietary and lifestyle factors are of paramount importance in low-incident regions of the world, especially Asia and Africa, nonetheless there are certain trends along racial or ethnic lines. For example, an inherited adenomatous polyposis coli (APC) gene mutation, I1307K, confers a higher risk of CRC within certain Ashkenazi Jewish families that is not apparent in other ethnic groups.^{13,14} Inherited mutations in the DNA mismatch repair genes may be more common among African Americans,¹⁵ in part accounting for anatomic variation in colon cancers among races in the United States,^{16,17} an area that is receiving much attention in epidemiology- and biology-based research.

One recent study extracted data from the Adjuvant Colon Cancer ENdpointTs (ACCENT) collaborative group database to analyze time-to-event end points for black and white patients participating in 12 randomized controlled adjuvant phase 3 trials of resected stage II and III colon cancer. In this cohort of 14,611 patients—controlling for sex, stage, age, and treatment type—both overall 5-year survival rates and 3-year recurrence-free survival rates were significantly worse for black patients (68.2% versus 72.8% and 68.4% versus 72.1%, respectively). However, recurrence-free interval was similar, arguing against a differential response to the adjuvant therapy itself. The authors concluded that

poorer outcomes were more likely related to confounding factors not measured such as toxicity, comorbid conditions, and racial disparities in care for recurrent disease.¹⁸

Socioeconomic Factors

Generally, cancer incidence and mortality rates have been higher in economically advantaged countries.^{19,20} This may be related to consumption of a high fat and high red meat diet, lack of physical activity with resulting obesity, and variations in mortality causes over a longitudinal period of time.

Anatomic Shift

Classically, colon cancer was believed to be a disease of the left or distal colon. However, the incidence of right-sided or proximal colon cancer has been increasing in North America^{17,21} and Europe.²² Similar trends have been observed in Asian countries.²³ This anatomic shift is likely multifactorial: (1) due to increased longevity; (2) as a response to luminal procarcinogens and carcinogens, which can vary between different sites of the colon and rectum; and (3) because of genetic factors, which can preferentially involve defects in mismatch repair genes with resulting microsatellite instability (MSI) in proximal colon cancers and chromosomal instability pathway predominant in left-sided colon and rectal cancers. These developments in anatomic variation will necessarily impact considerably on screening procedures, response to chemoprevention, response to chemotherapy, and, ultimately, disease-specific survival.^{24–26}

ETIOLOGY: GENETIC AND ENVIRONMENTAL RISK FACTORS

Inherited Predisposition

Family history confers an increased lifetime risk of CRC, but that enhanced risk varies depending on the nature of the family history (Table 57.1). Familial factors contribute importantly to the risk of sporadic CRC, depending upon the involvement of first- or second-degree relatives and the age of onset of CRC. Involvement of at least one first-degree relative with CRC serves to double the risk of CRC.²⁷ There is further enhancement of the risk if a case is affected prior to the age of 60. Similarly, the likelihood of harboring premalignant adenomas or CRC is increased in first-degree

TABLE 57.1

Etiology of Colon Cancer: Environmental Factors

Increased Incidence	Decreased Incidence
High-caloric diet	High-fiber diet??
High red meat consumption	Antioxidant vitamins
Overcooked red meat??	Fresh fruit/vegetables
High saturated fats	Nonsteroidal anti-inflammatories
Excess alcohol consumption	Coffee
Cigarette smoking	High calcium
Sedentary lifestyle	High Magnesium
Obesity	Bisphosphonates
Diabetes	

relatives of persons with CRC.^{28,29} The National Polyp Study reveals compelling data; the relative risk (RR) for parents and siblings of patients with adenomas compared to spousal controls was 1.8, which increased to 2.6 if the proband was younger than age 60 at adenoma detection.³⁰

Provocative assessments of population groups suggest a dominantly inherited susceptibility to colorectal adenomas and cancer, which may account for the majority of sporadic CRC, but this may have variable inheritance based on the degree of exposure to environmental factors.³¹ What are these susceptibility factors? The answer has yet to emerge. Nonetheless, genetic polymorphisms may be of paramount importance, such as in glutathione-S-transferase,³² ethylene tetrahydrofolate reductase,^{33,34} and N-acetyltransferases, especially NAT1 and NAT2.³⁵ In fact, genetic polymorphisms can vary among different racial and ethnic groups, which may provide clues to the geographic variation of CRC as well.

Environmental Factors

Seminal studies have underscored the importance of environmental factors as contributing to the pathogenesis of CRC. One has to take population-based studies into the context of methodologies employed, lead-time bias, time-lag issues, definition of surrogate and true end points, and the role of susceptibility factors.

One such population-based study recently evaluated risk factors for CRC from the Women's Health Initiative, a comprehensive prospectively collected database of 150,912 postmenopausal women, in which 1,210 developed colon cancer and 282 developed rectal cancer. Eleven risk factors were independently associated with colon cancer, some which have little or no previous support in the literature (age, waist girth, use of hormone therapy at baseline [protective], years smoked, arthritis [protective presumably due to medications used], relatives with CRC, lower hematocrit levels, fatigue, diabetes, less use of sleep medication, and cholecystectomy). Three of these factors were also significantly associated with an increased risk of rectal cancer (age, waist girth, and not taking hormone therapy).³⁶

Diet

Total Calories

Obesity and total caloric intake are independent risk factors for CRC as revealed by cohort and case-control studies.^{37,38} Increased body mass may result in a two-fold increase in CRC risk, with a strong association in men with colon but not rectal cancer. Weight gains during early to middle adulthood have also recently been linked with increased risk of colon but not rectal cancer. This relationship too seems more prominent in men than women in a large prospective study.³⁹

Meat, Fat, and Protein

Ingestion of red meat but not white meat is associated with an increased CRC risk,^{40,41} and as such, per capita consumption of red meat is a potent independent risk factor. Whether the total abstinence from red meat leads to a decreased CRC incidence has not been clarified, as there are studies with opposing results.⁴² Also unclear is whether the type of red meat or the degree of processing or cooking method make any difference. While Probst-Hensch et al.⁴³ found fried, barbecued, and processed meats to be associated with CRC risk, especially for rectal cancer, with odds ratio (OR) of 6, follow-up reports do not consistently support these claims. In the population-based Norwegian Women and Cancer cohort including 84,538 participants, highly processed meat intake (especially sausage) was associated with increased CRC risk but meat cooking methods and total meat intake were not.⁴⁴

A second study of 53,988 participants reported no difference with processed meat intake either. The authors did find that cancer risk was associated with different meat subtypes (i.e., animal of origin) which varied by tumor location—specifically, colon cancer risk was significantly elevated in the setting of high lamb intake (incidence rate ratio = 1.07) and rectal cancer risk was affected by pork (incidence rate ratio = 1.18).⁴⁵ However, McCullough et al.⁴⁶ recently reported a positive association in patients with non-metastatic CRC between red and processed meat consumption before cancer diagnosis with higher risk of death after definitive surgery.

Coffee

Coffee contains numerous bioactive compounds that may modulate cancer risk but previous epidemiologic studies investigating its role in CRC have yielded ambiguous results. In a recent meta-analysis of 41 studies (25,965 patients), Li et al.⁴⁷ found a significant inverse association from case-control data for CRC (OR = 0.85) and colon cancer (OR = 0.79), but not rectal cancer. This was particularly true among females and in Europe.⁴⁷ Stronger evidence comes from the National Institutes of Health–AARP Diet and Health Study, a large prospective US cohort including 489,706 members. In this report, both caffeinated and decaffeinated coffee drinkers had a decreased risk of colon cancer, particularly of proximal tumors (hazard ratio [HR] for more than six cups a day = 0.62), and decaffeinated coffee drinkers also had a decreased risk of rectal cancer. While known confounders such as smoking and red meat consumption were adjusted for, further investigation is warranted to confirm and clarify this association.⁴⁸

Fiber

Classically, a high-fiber diet was associated with a low incidence of CRC in Africa,⁴⁹ with numerous studies substantiating this premise.⁵⁰ Protection was believed to be afforded from wheat bran, fruit, and vegetables.⁴¹ A high-fiber diet was believed to dilute fecal carcinogens, decrease colon transit time, and generate a favorable luminal environment. The European Prospective Investigation into Cancer and Nutrition is an ongoing multicenter prospective cohort study, which was one of the largest and most influential studies to initially report an inverse association between dietary fiber and CRC. More long-term data, with a mean follow-up of 11 years and a near three-fold increase in CRC cases, further supports this claim while providing a more precise estimation by fiber food source as well. After multivariable adjustments, total dietary fiber was found to be inversely associated with both colon and rectal cancers (HR per 10 g/day increased in fiber = 0.87), and this did not differ by age, sex, lifestyle, or other dietary factors.⁵¹ However, other large, well-controlled studies show no inverse relationship between CRC and fiber intake.⁵² In a study of nearly 90,000 women from ages 34 to 59 who were followed for 16 years, no protective effect was noted between fiber and incidence of either adenomatous polyp or CRC.⁵² This was further corroborated by two large randomized controlled trials that evaluated high-fiber diets for moderate duration and discovered a lack of effect on the number, size, and histology of polyps found on colonoscopy.^{53,54} At this point, therefore, it is unclear whether dietary fiber plays any substantial role in the risk of developing CRC.

Vegetables and Fruit

A protective effect of vegetables and fruits against CRC is generally believed to be true.⁴⁰ This has been observed with raw, green, and cruciferous vegetables. Whether certain agents such as antioxidant vitamins (E, C, and A), folate, thioethers, terpenes, and plant phenols may translate into effective chemopreventive strategies requires further investigation, although the data for folate intake are sound.⁵⁵

Taking this nutritional data a step further, Bamia et al.⁵⁶ recently evaluated the impact of the Mediterranean diet on CRC risk in a large European cohort. This diet, introduced in the 1960s as “health-protecting,” includes a high intake of vegetables, fruits, nuts, fish, cereals, and legumes with moderate alcohol consumption and low consumption of dairy and meat. The authors found an 8% to 11% decreased CRC risk when comparing patients with the highest to lowest diet adherence rates (HR = 0.89). The association was strongest for women and colon tumors.⁵⁶

Other dietary factors under recent investigation include calcium, magnesium, and vitamin D. Calcium has been historically implicated as having a protective effect, perhaps due to its ability to bind injurious bile acids with reduction of colonic epithelial proliferation.⁵⁷ This is supported through cell culture models. However, population-based studies are not definitive.

A recent meta-analysis evaluating the influence of magnesium intake demonstrated a modest risk reduction, with pooled RRs of 0.81 for colon cancer and 0.94 for rectal cancer. This association persisted even after results were adjusted for calcium intake in six of the analyzed studies.⁵⁸

Vitamin D has been shown to inhibit cell proliferation and increase apoptosis in vitro, and its deficiency is considered an important risk factor for many types of solid cancers. In a meta-analysis of 18 prospective studies, vitamin D intake and blood 25 (OH)D levels were found to be inversely associated with the risk of CRC as well (RR = 0.79 and 0.62 for colon cancer, respectively; RR = 0.78 and 0.61 for rectal cancer, respectively). While this report offers only preliminary observational data, larger randomized trials for vitamin D supplementation are warranted⁵⁹ and would be needed before routine vitamin D supplementation could be recommended for the purpose of CRC prevention. It is noteworthy that the Institute of Medicine, while supporting vitamin D supplementation to maintain bone health, found the evidence insufficient to support vitamin D as being protective against colorectal or any other cancer.⁶⁰

Lifestyle

Physical inactivity has been associated with CRC risk, for colon more than rectal cancer. A sedentary lifestyle may account for an increased CRC risk, although the mechanism is unclear. Data suggest that physical activity after the diagnosis of stages I to III colon cancer may reduce the risk of cancer-related and overall mortality, and that the amount of aerobic exercise correlates with a reduced risk of recurrence following resection of stage III colon cancer.⁶¹ More recently, positive associations have been established between increased amounts of recreational physical activity before and after CRC diagnosis and lower mortality.⁶²

Most studies of alcohol have demonstrated at most a minimally positive effect. Associations are strongest between alcohol consumption in men and risk of rectal cancer. Perhaps interference with folate metabolism through acetaldehyde is responsible.⁶³

Prolonged cigarette smoking is associated with the risk of CRC.⁴⁰ Cigarette smoking for >20 pack-years was associated with large adenoma risk and >35 pack-years with cancer risk. To examine the impact of smoking cessation on the attenuation of this risk, Gong et al.⁶⁴ conducted a pooled analysis of eight studies, including 6,796 CRC cases and 7,770 controls. The authors found that former smokers also remained at increased risk for up to 25 years after quitting. However, this varied substantially by cancer subsite with risk declining immediately for proximal colon and rectal cases but not until 20 years after smoking cessation for distal colon tumors.⁶⁴

Diabetes

Type 2 diabetes has previously been implicated in the development of CRC, but it has been difficult to separate this association from other confounding lifestyle factors such as smoking and obesity.

Two recent meta-analyses provide further evidence that this condition is in fact a significant independent risk factor. Yuhara et al.⁶⁵ identified 14 studies, most of which controlled for smoking, obesity, and physical exercise, and demonstrated that diabetes was associated with increased risk of both colon and rectal cancer (RR = 1.38 and RR = 1.20, respectively).⁶⁵ A second report, analyzing 24 studies, found a similar association (RR = 1.26) with even higher risk for those patients on insulin therapy (RR = 1.61).⁶⁶

Drugs

Nonsteroidal Anti-Inflammatory Drugs

Population-based studies strongly support inverse associations between use of aspirin and other nonsteroidal anti-inflammatory drugs (NSAID) and the incidences of both CRC and adenomas.^{67–69} As a result, NSAIDs and selective cyclooxygenase 2 (COX-2) inhibitors have been investigated intensively in hereditary and sporadic CRC.

Long-term results have just been reported from the CAPP2 study, the first double-blind randomized controlled trial of aspirin chemoprevention with cancer as the primary end point. In this study, 861 carriers of Lynch syndrome were randomly assigned to aspirin or placebo. With a mean follow-up of 55.7 months, the authors report a significantly decreased incidence of CRC in the treatment group as well as a trend toward reduction in extracolonic Lynch syndrome–associated cancers. Importantly, there was no significant difference in adverse events such as gastrointestinal (GI) bleeding, ulcers, or anemia during the intervention period. These data provide strong rationale for the routine use of aspirin chemoprevention in Lynch syndrome and establish a foundation for further study in sporadic neoplasia. In a combined analysis of four large randomized trials of lower-dose aspirin (75 to 300 mg/day) involving 14,033 patients, aspirin taken for 5 years or more was associated with a reduced 20-year incidence and mortality due to CRC (absolute reduction = 1.76%; 95% confidence interval [CI] = 0.61 to 2.91; $p = 0.001$). Reduction was largely confined to right-sided tumors.⁷⁰ In addition to generalized chemoprevention, the question of aspirin and other NSAIDs in patients with a diagnosis of CRC has been addressed. Liao et al.⁷¹ have reported evidence that suggests that aspirin therapy after CRC diagnosis may be beneficial to those patients whose tumors have a PIK3CA mutation, but not in those with wild-type PIK3CA.⁷¹ However, PIK3CA mutation status had no impact on the influence of the COX-2 inhibitor rofecoxib on cancer recurrence.⁷²

Bisphosphonates

In addition to being one of the most commonly used medications for osteoporosis, bisphosphonates have been shown to have various antiproliferative, antiangiogenic, proapoptotic, and antiadhesive effects in preclinical studies. Practical impact on malignant disease, however, has been inconsistent. Singh et al.⁷³ performed a recent meta-analysis demonstrating a statistically significant 17% reduction in CRC incidence with bisphosphonate use. This finding was observed independently for both proximal and distal colon cancers as well as rectal cancers, highlighting another potential pathway for chemoprevention.⁷³

Biomarkers

In an effort to improve screening protocols and advance understanding of colorectal carcinogenesis, investigators are focusing on a variety of biomarkers for increased risk as well.

Toriola et al.⁷⁴ evaluated the role of C-reactive protein and serum amyloid A, two common inflammatory mediators, in the Women's Health Initiative Observational Study. With over 900 case-control pairs for each marker, the authors found that elevated concentrations of both C-reactive protein and serum

amyloid A conferred significantly increased risk of colon cancer (OR = 1.50, $p = 0.006$). This is not surprising given the role inflammation plays in colorectal carcinogenesis as well as the new promising data surrounding NSAID chemoprevention.⁷⁴

Leptin, a peptide hormone produced by adipocytes, is also thought to contribute to CRC pathogenesis. A recent prospective analysis found that soluble leptin receptor levels, which may regulate leptin function, was strongly inversely associated with both CRC and colon cancer risk (RR = 0.55 and RR = 0.42, respectively). This finding was independent of leptin levels and other circulating biomarkers.⁷⁵ Chi et al.⁷⁶ performed a similar investigation of insulin-like growth factor peptides, also implicated in CRC carcinogenesis, and found that high levels of insulin-like growth factor I and insulin-like growth factor II significantly increased cancer risk (OR = 1.25 and OR = 1.52, respectively).⁷⁶ Along these lines, high circulating levels of C-peptide, a direct marker of hyperinsulinemia, may also be a predictive factor for increased CRC risk, as indicated in a recent meta-analysis.⁷⁷

Human Papillomavirus

While human papillomavirus is well-established as the critical pathogenic force behind cervical and anogenital cancer, its role in colorectal malignancy is less clear. An association between the two was first reported in 1990 and since then, a growing number of studies have detected the virus in colon adenocarcinoma specimens. In the first meta-analysis to address this topic (including 16 articles and 1,436 patients), Damin, Ziegelmann, and Damin⁷⁸ not only reported a high prevalence of human papillomavirus (31.9%) in affected patients, but also found a strong correlation between human papillomavirus positivity and increased CRC risk (OR = 10.04; 95% CI = 3.7 to 27.5). These results may indicate an alternative pathway of colorectal carcinogenesis that could have vast implications for treatment and prevention.⁷⁸

FAMILIAL COLORECTAL CANCER

Familial Adenomatous Polyposis

Familial adenomatous polyposis (FAP) constitutes 1% of all CRC incidence (Table 57.2). Hallmark features include hundreds to thousands of colonic polyps that develop in patients in their teens to 30s, and if the colon is not surgically removed, 100% of patients progress to CRC. Extracolonic manifestations include benign conditions—congenital hypertrophy of the retinal pigment epithelium, mandibular osteomas, supernumerary teeth, epidermal cysts, adrenal cortical adenomas, desmoid tumors (although these tumors may lead to obstruction)—and malignant conditions—thyroid tumors, gastric small intestinal polyps with a 5% to 10% risk of duodenal or ampullary adenocarcinoma, and brain tumors.⁷⁹ The brain tumors may be of two types—glioblastoma multiforme or medulloblastoma—and the particular association of brain tumors and colonic polyposis is called Turcot syndrome.⁸⁰ The colonic polyps in Turcot syndrome are fewer and larger than in classic FAP. An attenuated form of FAP harbors up to 100 colonic polyps and has a predisposition to colorectal cancer in patients when they are in their 50s or 60s.⁸¹

FAP is an autosomally dominant disorder with nearly 100% penetrance. However, about 30% of patients have de novo mutations and are without an ostensible family history. Based on karyotypic analysis that reveals an interstitial deletion on human chromosome 5q and subsequent genetic linkage analysis to 5q21, the gene responsible for FAP was identified as APC. Patients with FAP inherit a mutated copy of the APC gene, thereby predisposing them to early onset polyposis. During life, patients with FAP acquire inactivation of the remaining APC gene copy, which accelerates the progression to CRC. Interesting genotypic-phenotypic

TABLE 57.2

Familial and Nonfamilial Causes of Colorectal Cancer

Syndromes with Adenomatous Polyps

APC gene mutations (1%):

- Familial adenomatous polyposis
- Attenuated APC
- Turcot syndrome (two-thirds of families)

MMR gene mutations (3%):

- Hereditary nonpolyposis colorectal cancer types I and II
- Muir-Torre syndrome
- Turcot syndrome (one-third of families)

Syndromes with hamartomatous polyps (<1%)

Peutz-Jeghers (*LKB1*)

Juvenile polyposis (*SMAD4*, *PTEN*)

Cowden (*PTEN*)

Bannayan-Ruvalcaba-Riley

Mixed polyposis

Other Familial Causes (up to 20%–25%)

Family history of adenomatous polyps (*MYH*)

Family history of colon cancer:

- Risk more than three times greater if two first-degree relatives or one first-degree relative <50 y with colon cancer
- Risk two times greater if second-degree relative affected

Familial colon-breast cancer

Nonfamilial Causes

Personal history of adenomatous polyps

Personal history of colorectal cancer

Inflammatory bowel disease (ulcerative colitis, Crohn's colitis)

- Radiation colitis
- Ureterosigmoidostomy
- Acromegaly
- Cronkhite-Canada syndrome

associations exist between the location of the APC gene mutation and certain clinical manifestations, such as congenital hypertrophy of the retinal pigment epithelium, desmoid tumors, and classic FAP versus attenuated FAP.

The APC gene comprises 15 exons and encodes a protein of nearly 2,850 amino acids (310 kDa). Nearly all germline mutations in the APC gene lead to a truncated protein, which can be detected through molecular diagnostic assays that can be integrated into genetic counseling and genetic testing of affected patients and at-risk family members.^{82,85} The functions of the APC protein and the interrelated pathways and regulatory molecules will be discussed later.

Hereditary Nonpolyposis Colorectal Cancer

Hereditary nonpolyposis CRC (HNPCC) accounts for about 3% of all CRCs. Salient features include up to 100 colonic polyps (hence the term nonpolyposis), preferentially, albeit not exclusively, in the right or proximal colon.⁸⁴ There is an accelerated rate of progression to CRC in these diminutive, at times flat, polyps with mean age of onset of CRC being 43 years. This is designated HNPCC type I. HNPCC type II is distinguished by extracolonic tumors that originate in the stomach, small bowel, bile duct, renal pelvis, ureter, bladder, uterus and ovary, skin, and perhaps the pancreas.

TABLE 57.3

Criteria for Identifying At-Risk Individuals for Mismatch Repair Deficiency (High Microsatellite Instability)

Amsterdam I Criteria

At least three relatives with colorectal cancer

One relative should be a first-degree relative of the other two

At least two successive generations should be affected

At least one colorectal cancer case before age 50

FAP should be excluded

Tumors should be verified histopathologically

Amsterdam II Criteria

At least three relatives with HNPCC-associated cancer (colorectal, endometrial, small bowel, ureter, or renal pelvis)

At least two successive generations should be affected

At least one case before age 50

FAP should be excluded

Tumors should be verified histopathologically

Bethesda Criteria (for Identification of Patients with Colorectal Tumor who Should Undergo Testing for MSI)

Cancer in families that meet Amsterdam criteria

Two HNPCC-related cancers, including colorectal or extracolonic

Colorectal cancer and a first degree relative with colorectal cancer and/or HNPCC-related extracolonic cancer and/or colorectal adenoma: one cancer before age 45 and adenoma before age 40

Colorectal cancer or endometrial cancer before age 45

Right-sided colorectal cancer with an undifferentiated pattern on histopathology before age 45

Signet-ring cell type colorectal cancer before age 45

Adenoma before age 40

FAP, familial adenomatous polyposis; HNPCC, hereditary nonpolyposis colorectal cancer; MSI, microsatellite instability.

The lifetime risk of CRC in HNPCC is 80%, up to 50% to 60% for endometrial cancer, and 1% to 13% for all other cancers.^{84,85} Of note, a variant of HNPCC involves skin tumors and is designated as Muir-Torre syndrome. HNPCC is defined classically by the modified Amsterdam criteria (Table 57.3).

HNPCC is an autosomally dominant disorder with about 80% penetrance. Genetic and biochemical approaches led to the discovery of the involvement of human DNA mismatch repair genes in HNPCC. Recognized as the human orthologues of mismatch repair genes described in bacteria and yeast, human mismatch repair genes encode enzymes that repair errors during DNA replication that may occur spontaneously or upon exposure to an exogenous agent (e.g., ultraviolet light, chemical carcinogen). Mutations in one of these mismatch repair genes results in MSI, which creates a milieu of somatic mutations of target genes—*TGF-β2* receptor, *bax*, *IGF* type I receptor, among others—in HNPCC-associated tumors.⁸⁶ About 60% of germline mutations in HNPCC are found in either the *hMLH1* gene or the *hMSH2* gene, but mutations in other members of this family—*hMSH6*, *hPMS1*, *hPMS2*—are rare, thereby indicating that other genes are involved but have yet to be discovered. Genetic testing is not facile for HNPCC as it is for FAP, but it involves sequencing both the *hMLH1* and *hMSH2* genes (Table 57.4). If a germline mutation is found, then the remaining at-risk family members can be genetically screened.

TABLE 57.4

Genetic Testing in Inherited Colorectal Cancer

FAP	APC protein truncating testing (preferred). If APC mutation found, screen for mutation in family. Less desirable alternatives: gene sequencing, linkage testing.
HNPCC	MSI testing in tumor. ^a If MSI present, proceed to sequencing of both <i>hMLH1</i> and <i>hMSH2</i> genes. If mutation found, screen for mutation in family.

FAP, familial adenomatous polyposis; APC, adenomatous polyposis coli; HNPCC, hereditary nonpolyposis colorectal cancer; MSI, microsatellite instability.

^a Immunohistochemistry may be an option.

MSI testing and hMLH1/hMSH2 immunohistochemistry (IHC) can be performed on tumor specimens as a possible prelude to genetic testing.

Hamartomatous Polyposis Syndromes

Hamartomatous polyposis syndromes are rare syndromes, mostly affecting the pediatric and adolescent population, and represent <1% of CRCs annually. Peutz-Jeghers syndrome involves large but few colonic and small bowel polyps that can manifest by GI bleeding or obstruction and an increased risk of CRC. The polyps are distinguished by a smooth muscle band in the submucosa. Hallmark clinical features on physical examination include freckles on the hands, around the lips, in the buccal mucosa, and periorbitally. Associated characteristics include sinus, bronchial, and bladder polyps, and about 5% to 10% of patients have sex cord tumors. Patients can also develop lung and pancreatic adenocarcinomas. The gene responsible for this syndrome is *LKB1*, a serine threonine kinase.

Juvenile polyposis have overlapping clinical manifestations with Peutz-Jeghers, but the polyps tend to be confined to the colon, although cases of gastric and small bowel polyps have been described and there is an increased risk of CRC. Extracolonic manifestations are not prevalent. This is a polygenic disease, involving germline mutations in *PTEN*, *SMAD4*, *BMPRI*, or other genes yet to be identified.

Cowden syndrome harbors hamartomatous polyps anywhere in the GI tract, and surprisingly, there is no increased risk of CRC. However, about 10% of patients will have thyroid tumors and nearly 50% of patients have breast tumors. Germline *PTEN* mutations have been reported.

It is estimated that about 20% to 30% of CRCs are compatible with an inherited predisposition, independent of known syndromes.⁸⁷ The identification of other responsible genes will have great clinical impact. Intensive approaches are being pursued through sibling-pair studies and other familial studies. As previously mentioned, patients may be predisposed to an increased risk of adenomatous polyps as well in the context of a family history of sporadic adenomatous polyps.

ANATOMY OF THE COLON

The colon and rectum make up the segment of the digestive system commonly referred to as the large bowel. Defined as the portion of intestine from the ileocecal valve to the anus, the large bowel is approximately 150 cm in length. It is divided into five segments defined by its vascular supply and by its extraperitoneal or retroperitoneal location: the cecum (with appendix) and ascending colon, the transverse colon, the descending colon, the

sigmoid colon, and the rectum. The anatomy of the rectum will be discussed in detail in the chapter on rectal cancer. The large bowel has a muscular wall and can be distinguished from the small intestine by its increased diameter, the presence of haustra, appendices epiploicae, and tenia coli. The tenia consist of condensations of longitudinal muscle fibers starting near the base of the appendix and continuing throughout the abdominal colon to form a continuous longitudinal muscle coat in the upper rectum. Haustra are outpouchings of bowel wall separated by folds that give a classic appearance on radiography or barium enema.

The right colon is made up of the cecum (with appendix) and ascending colon. It is anterior to the right kidney and the duodenum. Its vascular supply is from branches of the superior mesenteric artery (SMA). The SMA divides into the middle colic artery and the trunk of the SMA. The middle colic artery immediately forms two to three large arcades in the transverse mesocolon. The SMA ileocolic arterial branches then extend from the SMA. The right colic artery arises as a separate branch from the SMA in 10.7% of cases.⁸⁸ The ileocolic artery gives off a right colic artery to the upper ascending colon and forms an anastomosis with branches from the middle colic artery. The ileal branch of the ileocolic artery gives off branches to the distal small bowel and cecum, whereas the colic branch supplies the ascending colon. An anastomosis occurs between the distal SMA and the ileal branch of the ileocolic artery at the junction of the terminal ileum and cecum. The right colon is a retroperitoneal structure.

The transverse colon is supplied by branches of the middle colic artery. It is the first portion of the colon considered to be intraperitoneal, and its length can vary. Its boundaries are defined by the hepatic flexure on the right and the splenic flexure on the left. Both of these points are fixed. The hepatic flexure abuts the gallbladder fossa, while the splenic flexure lies anterior to the splenic hilum and the tail of the pancreas. The descending colon is where the colon once again becomes a retroperitoneal structure, and it is defined as the segment of colon from the splenic flexure to the sigmoid colon. The descending colon is the first segment of the left side of the colon and receives its blood supply from the inferior mesenteric artery. The inferior mesenteric artery arises from the aorta and gives off the left colic artery. It also gives off three to four sigmoidal arteries, which supply the intraperitoneal sigmoid colon. The anastomosis between the vessels of the middle colic artery and those of the left colic artery and right colic artery is known as the marginal artery of Drummond. The arcade, which effectively connects the left and right circulations, is known as the arc of Riouan. The arterial supply to the colon is depicted in Fig. 57.1.

The venous and lymphatic drainage of the colon parallels the arterial supply, and all three vessels course and divide within the colonic mesocolon (Fig. 57.2). The mesocolon therefore contains the regional lymph nodes (LN) for the segment of colon it supplies and drains. The efferent lymphatic channels pass from the submucosa to the intramuscular and subserosal plexus of the bowel to the first tier of LNs lying adjacent to the large intestine and known as *epicolic nodes*.⁸⁹ *Paracolic nodes* lie on the marginal vessels along the mesenteric side of the colon and are frequently involved in metastases. *Intermediate nodes* are found along the major arterial branches of the SMA and inferior mesenteric artery in the mesocolon. The *principal nodes* are found around the origin of these vessels from the aorta, and they drain into retroperitoneal nodes. The drainage of the superior and inferior mesenteric veins, which drain the ascending, transverse, descending, and sigmoid colon, is to the portal vein. The rectum is drained by rectal tributaries to the vena cava.

The extent of resection of the colon is defined by the vascular supply and by the need to take the regional draining LNs.^{90,91} A careful understanding of the colonic anatomy, structure, location, and vascular supply is therefore critical in order to perform a safe and effective cancer operation. The segmental resections important for removal of lesions in various locations within the colon will be described in greater detail in later sections.

Figure 57.1 The anatomy of the colon with particular emphasis on the vascular supply.

DIAGNOSIS OF COLORECTAL CANCER

Symptoms associated with CRC include lower GI bleeding, change in bowel habits, abdominal pain, weight loss, change in appetite, and weakness, and in particular, obstructive symptoms

are alarming.⁹² However, apart from obstructive symptoms, other symptoms do not necessarily correlate with stage of disease or portend a particular diagnosis.⁹³

Physical examination may reveal a palpable mass, bright blood per rectum (usually left-sided colon cancers or rectal cancer) or melena (right-sided colon cancers), or lesser degrees of bleeding (hemoccult-positive stool). Adenopathy, hepatomegaly, jaundice, or even pulmonary signs may be present with metastatic disease. Obstruction by colon cancer is usually in the sigmoid or left colon, with resulting abdominal distention and constipation, whereas right-sided colon cancers may be more insidious in nature. Complications of CRC include acute GI bleeding, acute obstruction, perforation, and metastasis with impairment of distant organ function.

Laboratory values may reflect iron-deficiency anemia, electrolyte derangements, and liver function abnormalities. The carcinoembryonic antigen (CEA) may be elevated and is most helpful to monitor postoperatively, if reduced to normal as a result of surgery.⁹⁴

Evaluation should include complete history, family history, physical examination, laboratory tests, colonoscopy, and pan-body computed tomography (CT) scan.⁹⁵ For rectal cancer, additional imaging techniques, such as magnetic resonance imaging or endoscopic ultrasound, are utilized to further characterize the primary tumor prior to therapy (see Chapter 60). Upon completion of diagnosis and staging for both colon and rectal tumors, it is essential to incorporate the expertise from medical, radiation, and surgical oncologists in order to formulate and implement an optimal treatment plan.

With the advent of molecular biologic techniques, attention has been drawn to stool-based tools and new blood-based tests. Technology now exists to extract genomic DNA or protein from stool and assay for evidence of genetic alterations.^{96,97} Large-scale validation studies are in progress, one of which has just been published, describing an automated multitarget sDNA assay (fecal immunochemical testing) with a 90% specificity and 98% sensitivity for the detection of CRC, as well 83% sensitivity for advanced adenoma with high-grade dysplasia.⁹⁸ In addition, Epi proColon (EpiGenomics AG, Berlin, Germany), a blood-based test, was

Figure 57.2 The lymphatic drainage of lesions in various anatomic locations throughout the colon.

shown to be noninferior to fecal immunochemical testing in preliminary results from a multicenter double blind comparative study (press release from Epigenomics AG, December 4, 2012). One particularly attractive pathway for stool-based diagnostics would be able to stratify patients as high, moderate, or low risk for CRC and thus influence screening modalities and frequency of screening. In a complementary fashion, functional genomics are being applied to pair-wise comparisons of normal colon and CRCs to sample the entire human genome of nearly 30,000 genes to discover those genes, known and novel, that may be upregulated or downregulated and possibly linked to detection, prognosis, and therapy.

SCREENING FOR COLORECTAL CANCER

Debate is vigorous as to the best approaches for screening, and multiple factors influence that decision: simplicity and rapidity so as to enhance patient compliance, benefit to risk ratio, sensitivity, specificity, cost-effectiveness, and other economic factors. To that end, currently, optical colonoscopy likely offers the most effective approach when one considers all of these factors.

The average-risk patient is defined as a man or woman above the age of 50 without personal or family history of adenomatous polyps or CRC and absence of any occult or acute GI bleeding. Screening recommendations or guidelines for average-risk and high-risk individuals are presented in Table 57.5.

Optical colonoscopy is currently the most sensitive method for screening. Advantages include direct visualization, with the ability to remove polyps (with rate-limiting factors of size and anatomic location) and to obtain biopsies. Disadvantages involve the preparation, invasive nature of the procedure, and potential side effects that include perforation (although this is <1%).

The digital rectal examination should be part of the general physical examination. Anorectal masses may be palpated. Flexible sigmoidoscopy does not require conscious sedation and hemodynamic monitoring, and will typically allow visualization of the rectum, sigmoid colon, and descending colon to the splenic flexure. Flexible sigmoidoscopy should not be considered as a single screening measure but requires coupling with barium enema. Barium enema allows visualization of the entire colon, and experience is necessary to ensure proper visualization of the rectum. Barium enema affords advantages of ease of preparation, lack of conscious sedation and hemodynamic monitoring, and ability to visualize polyps and masses. However, small polyps may be missed. Furthermore, if a luminal polyp or mass is identified, then colonoscopy will be necessary for polypectomy or biopsies.

New noninvasive technologies, such as CT and magnetic resonance colonography, are receiving increased attention in clinical studies, which demonstrate overall feasibility, as well as some advantages.⁹⁹

Two meta-analyses published in 2011 provide strong support for the implementation of CT colonography as a viable alternative to optical colonoscopy in both average and high-risk populations.

TABLE 57.5

Recommendations for Colorectal Cancer Screening in Average-Risk and Increased-Risk Patients from the Gastrointestinal Consortium Panel

Average-Risk Patient (Different Options)

1. FOBT: Offer yearly screening with FOBT using a guaiac-based test with dietary restriction or an immunochemical test without dietary restriction. Two samples from each of three consecutive stools should be examined without rehydration. Patients with a positive test on any specimen should be followed up with colonoscopy.
2. Flexible sigmoidoscopy: Offer flexible sigmoidoscopy every 5 y.
3. FOBT plus flexible sigmoidoscopy: Offer screening with FOBT every year combined with flexible sigmoidoscopy every 5 y. When both tests are performed, the FOBT should be done first.
4. Colonoscopy: Offer every 10 y.
5. DCBE: Offer every 5 y.

Increased Risk for Colorectal Cancer

1. Family history of colorectal cancer or polyps. People with a first-degree relative (parent, sibling, or child) with colon cancer or adenomatous polyp diagnosed at age <60 y or two first-degree relatives diagnosed with colorectal cancer at any age should be advised to have screening colonoscopy starting at age 40 y or 10 y younger than the earliest diagnosis in the family, whichever comes first, and repeated every 5 y.
2. FAP: Flexible sigmoidoscopy to start at ages 10 to 12 y. Genetic testing (for FAP, upper endoscopy with side-viewing scope) should be done every 1 to 3 y.
3. HNPCC: Colonoscopy every 1 to 2 y starting at ages 20 to 25 y or 10 y younger than the earliest case in the family, whichever comes first. Genetic testing (for HNPCC, consideration should be given to screening for uterine and ovarian cancer with hysteroscopy and transvaginal ultrasound, the frequency of which varies within centers).
4. Personal history of adenomatous polyps
 - A. If one or more polyps that are malignant or large and sessile or colonoscopy is incomplete, then follow-up colonoscopy should be in the short term.
 - B. If three or more polyps, follow-up colonoscopy in 3 y.
 - C. If one or two polyps (<1 cm), follow-up colonoscopy in 5 y (or more).
5. Personal history of colorectal cancer
 - A. Colonoscopy is incomplete at time of diagnosis of colorectal cancer due to obstruction, then repeat colonoscopy 6 mo after surgical resection.
 - B. Colonoscopy is complete at time of diagnosis of colorectal cancer, then repeat colonoscopy in 3 y, and if that is normal, then repeat every 5 y.
6. Inflammatory bowel disease (ulcerative colitis, Crohn's colitis). Surveillance colonoscopy is recommended.

FOBT, fecal occult blood testing; DCBE, double-contrast barium enema; FAP, familial adenomatous polyposis; HNPCC, hereditary nonpolyposis colorectal cancer. From Rex DK, Johnson DA, Lieberman DA, et al. Colorectal cancer prevention 2000: screening recommendations of the American College of Gastroenterology. American College of Gastroenterology. *Am J Gastroenterol* 2000;95:868-877; Winawer S, Fletcher R, Rex D, et al. Colorectal cancer screening and surveillance: clinical guidelines and rationale-Update based on new evidence. *Gastroenterology* 2003;124:544-560.

In a review of 4,086 asymptomatic patients, de Haan et al.,¹⁰⁰ estimates sensitivities of 82.9% and 87.9% and specificities of 91.4% and 97.6% for adenomas ≥ 6 mm and ≥ 10 mm, respectively.

In a complementary analysis looking exclusively at cancer detection, Pickhardt et al.¹⁰¹ concludes that CT colonography is not only clinically equivalent to colonoscopy but perhaps even more suitable for initial investigation given consistently high sensitivity (96.1%) without heterogeneity across 49 studies, and 11,151 patients, despite wide variation in technique.

Other reports suggest advantages in long-term costs and patient compliance, although these issues remain controversial.^{102,103}

Lastly, CT colonography may also offer improvements in preoperative staging as one study found this technique to be highly predictive of T3-4 tumors. Whether this information will prove as clinically relevant in colon cancer as it is for the rectum remains to be seen.¹⁰⁴

STAGING AND PROGNOSIS OF COLORECTAL CANCER

This discussion will focus primarily on those prognostic and predictive indicators that are best supported by available data and are appropriate for use and consideration in current practice. The reader should remain aware of the potential for rapid changes and advances in this area, however.

Staging

Although many factors have been identified that have an impact on recurrence and survival, none exceeds stage in terms of prognostic significance.¹⁰⁵ Staging of CRC should be done using the current TNM (tumor, node, metastasis) classification of the American Joint Committee on Cancer (AJCC)/International Union Against Cancer (UICC) staging system (Table 57.6).¹⁰⁶ Other systems should be regarded as of historical significance only and must be comprehended solely for the purposes of understanding the studies that were performed and reported in the past using these older classifications.

TABLE 57.6

Tumor (T) Node (N) Metastasis (M) Classification of Colorectal Cancer

Stage	T	N	M
0	Tis	N0	M0
I	T1	N0	M0
	T2	N0	M0
IIA	T3	N0	M0

The Dukes Classification and Its Modifications

In the 1930s, Cuthbert Dukes, a Scottish pathologist working predominantly on a classification scheme for rectal cancer, developed the classification system that bears his name. The system, and the several modifications to it made by Dukes and others, is at this time of historical interest only, and the reader is referred to chapters in earlier editions of this book for further details.

Tumor, Node, Metastasis Classification

The current AJCC/UICC staging system for CRC is now the only classification system that should be used.¹⁰⁶ The TNM system classifies colorectal tumors on the basis of the invasiveness (not size) of the primary (T stage), the number (not size or location) of local-regional LNs containing metastatic cancer (N stage), and the presence or absence of distant metastatic disease (M stage) (see Table 57.6).

T Stage. A designation of Tx refers to the inability to describe the extent of tumor invasion due to incomplete information. In situ adenocarcinoma (Tis) includes cancers confined to the glandular basement membrane or lamina propria. The terms *high-grade dysplasia* and *severe dysplasia* are synonymous with in situ carcinoma and are also classified as Tis. T1 tumors invade into but not through the submucosa. T2 tumors invade into but not through the muscularis propria, and T3 tumors invade through the muscularis propria into the subserosa or into nonperitonealized pericolic or perirectal tissue. T4 tumors perforate the visceral peritoneum (T4a) or invade other named organs or structures (T4b). Tumors invading other colorectal segments by way of the serosa (i.e., carcinoma of the cecum invading the sigmoid) are classified as T4b. A tumor that is adherent to other structures or organs macroscopically is classified clinically as T4b; however, if the microscopic examination of the adhesions is negative, then the pathologic classification is pT3. The V and L substaging should be used to identify the presence or absence of vascular or lymphatic invasion. The “p” prefix denotes pathologic (rather than clinical) assessment, and the “y” prefix is attached to those tumors that are being reported after neoadjuvant (presurgical) treatment. For example, the pathologic T stage of a tumor showing only penetration into the submucosa after preoperative therapy would be ypT1. Recurrent tumors are reported with an “r” prefix (rpT3).

N Stage. Because of the prognostic significance associated with increased numbers of LNs inspected (see the following discussion), the current TNM classification scheme calls for at least 12 LNs to be analyzed, and both the number of nodes that are positive for tumor and the total number of nodes inspected should be reported. The term Nx is applied if no description of LN involvement is possible because of incomplete information. A pN0 designation may be made even if fewer than the recommended number of nodes are present; however, the prognostic significance of this pN0 designation is weaker. N0 denotes that all nodes examined are negative. N1a includes tumors with metastasis in one regional LN. N1b refers to involvement of two or three nearby LNs. N1c defines the presence of cancer cells found in areas of fat near LNs, but not in the LNs themselves. N2a indicates metastasis in four to six regional LNs. N2b denotes involvement of greater than seven nodes. Metastatic nodules or foci found in the pericolic, perirectal, or adjacent mesentery without evidence of residual LN tissue are regarded as being equivalent to a regional node metastasis and are counted accordingly.

Stage I disease is defined as T1-2N0 in a patient without distant metastases (M0). Stage II disease is defined as T3-4N0M0. The T-stage carries prognostic significance for stage II, and therefore T3N0 is classified as IIA, and T4a-bN0 is classified as IIB and IIC, respectively.

Node positivity in the absence of M1 disease defines stage III CRC. Recently, the prognostic significance of tumor invasiveness (T stage) has been reincorporated into the assessment of risk

in stage III patients. In an exhaustive review of over 50,000 patients, Greene et al.¹⁰⁷ demonstrated the prognostic significance of T stage within node-positive patients. Within the N1 category T stage was found to be highly prognostic, with T1-2 patients fairsignificantly better than T3-4. Within the N2 population, the prognosis was worse than either subgroup of N1 patients, with T stage no longer carrying prognostic significance. Thus T stage is prognostic in patients with N0 and N1 but not N2 disease. The current TNM staging system takes these findings into account and now stratifies stage III patients into IIIA (T1-2N1), IIIB (T3-4N1), and IIIC (T any, N2). Stages IIIA, B, and C are highly prognostic for survival.

M Stage. Patients are designated M0 if no evidence of distant metastases is present. Identification of distant metastases denotes a classification of M1. Involvement of the external iliac, common iliac, para-aortic, supraclavicular, or other nonregional LNs is classified as distant metastatic (M1) disease. The M1 category is subdivided into M1a, defined as spread of tumor to one distant organ or set of distant LNs, and M1b, where spread has occurred to more than one distant organ or sets of LNs or spread has occurred to the peritoneum. Although the TNM staging system is regarded as the most comprehensive tool for prognostic and predictive purposes, a major criticism of the last two revisions is that survival of stage IIIA patients continues to be superior to stage IIB. This disparity, which is actually more pronounced in the seventh edition of AJCC manual, has been attributed to inadequate LN assessment and understaging. However, a recent review of SEER data showed this problem persists even in a subset analysis of patients with >12 LNs, highlighting the need for additional refinement and perhaps the incorporation of nonanatomic prognostic factors.¹⁰⁸

Residual Tumor (R Stage) at Margins of Resection. Tumors that are completely resected with histologically negative margins are classified as R0. Tumors with a complete gross resection but with microscopically positive margins are classified as R1, the positive margin indicating that at least microscopic tumor remains in the patient. Patients who have incomplete resections with grossly positive margins are classified as having had an R2 resection. The R0, R1, and R2 designations carry strong prognostic implications.

Identification of the proximal and distal margins of resection is relatively straightforward, and definitions of these margins are well understood. A more complex and often misunderstood (as well as underreported) margin of resection is the circumferential radial margin (CRM). All three margins (proximal, distal, and CRM) should be specifically commented upon in the pathology report, as all three have prognostic significance.

The CRM is, by definition, a surgically dissected surface. It is defined as the cut retroperitoneal or perineal soft tissue margin closest to the deepest penetration of tumor. It is considered positive if tumor is present microscopically (R1) or macroscopically (R2) on a *cut* radial or lateral aspect of the surgical specimen. For the ascending colon, descending colon, and upper rectum, which are incompletely encased by peritoneum, the CRM is created by dissection of the retroperitoneal aspect of the bowel. In the case of the lower rectum, which is not encased by peritoneum, the CRM is created by sharp dissection of the mesorectum.

A tumor simply penetrating into pericolic or perirectal fat does not necessarily constitute a positive CRM, but rather is simply a description of a T3 primary. A tumor that involves a peritonealized surface of the bowel and not a surgically cut surface does not constitute a positive CRM, but rather constitutes a T4a primary. If, however, the cut surface at the deepest penetration of the tumor is positive, then the CRM is positive and the resection is staged R1 (microscopic) or R2 (macroscopic). A positive CRM is highly predictive of local recurrence and should prompt consideration of adjuvant treatment.

Prognosis

Histologic Grade

Although histologic grade has been shown to have prognostic significance, there is significant subjectivity involved in scoring of this variable, and no one set of criteria for determination of grade are universally accepted.¹⁰⁵ The majority of staging systems divide tumors into grade 1 (well differentiated), grade 2 (moderately differentiated), grade 3 (poorly differentiated), and grade 4 (undifferentiated). Many studies collapse this into low grade (well to moderately differentiated) and high grade (poorly differentiated or undifferentiated). Greene et al.¹⁰⁷ demonstrated that this two-tiered split has important prognostic significance.

College of American Pathologists Consensus Statement.

The College of American Pathologists (CAP) has published an expert panel consensus statement outlining their interpretation of the validity and usefulness of a large number of putatively prognostic and predictive factors in CRC.¹⁰⁹ Variables were categorized as belonging to categories I through IV. Category I was defined as those factors proven to be of prognostic import based on evidence from multiple, statistically robust, published trials and generally used in patient management. Category IIA included factors intensively studied biologically or clinically and repeatedly shown to have prognostic value for outcome or predictive value for therapy that is of sufficient import to be included in the pathology report, but that remains to be validated in statistically robust studies. Category IIB included factors shown to be promising in multiple studies but lacking sufficient data for inclusion in category I or IIA. Category III included factors felt to be not yet sufficiently studied to determine their prognostic value, and category IV included those factors that are adequately studied to have convincingly shown no prognostic significance. A number of these factors are discussed in further detail in the following.

The T, N, and M categories of the current AJCC/UICC staging system were all classified as category I. Other category I inclusions were blood or lymphatic vessel invasion and residual tumor following surgery with curative intent (the R category). Although not assessed pathologically, an elevation of the preoperative CEA level was also felt to merit category I inclusion. Factors in category IIA included tumor grade, radial margin status (for resection of specimens with nonperitonealized surfaces), and residual tumor in the resection specimen following neoadjuvant therapy. Factors in category IIB (many of which are discussed in further detail in the following) included histologic type, histologic features associated with MSI (i.e., host lymphoid response to tumor and medullary or mucinous histologic type), high degree of MSI (MSI-H), loss of heterozygosity (LOH) of 18q (*DCC* [deleted in colon cancer] gene loss), and tumor border configuration (infiltrating versus pushing border). Factors grouped in category III included DNA content, all other molecular markers except for LOH of 18q/*DCC* and MSI-H, perineural invasion, microvessel density, tumor cell-associated proteins or carbohydrates, peritumoral fibrosis, peritumoral inflammatory response, focal neuroendocrine differentiation, nuclear organizing regions, and proliferation. Those factors in category IV (proven to be of no significance) included tumor size and gross tumor configuration.

Total Number of Lymph Nodes

It has been well established that an adequate number of LNs must be sampled before a patient can be considered node negative, and careful pathologic technique has been demonstrated to be crucial to adequate nodal interpretation. Failure to adequately dissect and display the mesentery will lead to underreporting and understaging.^{110,111} It should be noted that an insufficient number of LNs reported could be due to a suboptimal nodal dissection at operation, a less than thorough search for nodes by the pathologist, or some

combination of the two. Additional patient- and tumor-related factors may also affect LN count independent of pathologist or surgeon. Belt et al.¹¹² found a significant association between MSI phenotype and high LN yield in both stage II and III colon cancers, with the strongest effect in the latter group. The authors postulate that this may be due to a more prominent lymphocytic antitumor response known to be exhibited by MSI-H cancers.¹¹² Another report suggests that low body mass index is associated with increased LN yield, although it did not affect relapse-free or overall survival in stage III cancers. Proximal tumor location, well- or moderately differentiated histology, and stage IIIC cancer were also significant variables for adequate LN recovery.¹¹³ Finally, a multivariate analysis of two large prospective US cohort databases (121,701 women and 51,529 men) demonstrated that specimen length, tumor size, ascending tumor location, T3N0M0 stage, and year of diagnosis were positively associated with negative node count ($p < 0.002$). Mutation of KRAS was borderline significant and requires further study. The authors recommend that these variables be taken into account when judging adequacy of LN harvest and devising individualized treatment plans in the future.¹¹⁴ An analysis was reported on outcome versus nodal sampling in the patients who participated in an Intergroup trial (INT-0089), a large four-arm trial of different 5-fluorouracil (5-FU)-based adjuvant chemotherapies in patients with colon cancer. Multivariate analyses were performed on the node-positive (2,768 patients) and node-negative (648 patients) groups separately. The median number of LNs reported in the assessable patients on this trial was 11 (range, 1 to 87). Survival (overall, cancer-specific, and disease-free [DFS]) was found to decrease with an increasing number of involved LNs ($p = 0.0001$ for all three survival end points). However, after controlling for the number of involved nodes, survival increased with the total number of nodes (positive plus negative) reported ($p = 0.0001$ for overall survival, cancer-specific survival, and DFS). Even in patients who were node negative, overall survival ($p = 0.0005$) and cancer-specific survival ($p = 0.007$) were significantly increased as the number of reported LNs increased.

In a different secondary analysis of the Intergroup trial (INT-0089), a mathematical model was created to estimate the probability of a true node-negative result on the basis of the number of LNs examined in a subset of patients who had at least 10 LNs reported in their resection specimen.¹¹⁵ A total of 1,585 patients with stage III or high-risk stage II colon cancer were evaluated. This model concluded that when 18 nodes are examined, there is a <25% probability of true node negativity in T1 and T2 tumors. However, examination of <10 LNs was needed in T3 and T4 tumors to achieve the same probability. The overall conclusions of this analysis were that a very significant proportion of patients are understaged, and that such understaging could have important implications for decisions regarding adjuvant therapy and for overall prognosis.

The CAP consensus statement suggests that a minimum of 12 to 15 LNs should be examined in order to determine node negativity.¹⁰⁹ Availability of fewer nodes should therefore be regarded as a relative high-risk factor in terms of prognosis and should be factored into decisions regarding adjuvant therapy. Further support for this recommendation comes from a newly published Danish cohort study that indicates that the advantage of larger LN harvest extends beyond more accurate staging. In addition to improved outcomes for node-negative patients, the authors found a significant increase in overall survival for stage III patients with >12 LNs removed as well (58.6% versus 45.2% for <12 LNs), despite a higher prevalence of N2 disease in this group. This may be related to better surgical technique or an underlying benefit of wider lymphadenectomy in general. LN ratio was also shown to be an important independent prognostic indicator and, in fact, superior to N-stage in predicting survival for stage III patients. This finding is consistent with a number of previous reports, many of which have advocated for incorporation of this parameter into the AJCC staging system.¹¹⁶⁻¹²⁰

Microscopic Nodal Metastases

The advent of improved pathologic techniques and sensitive methods such as IHC or polymerase chain reaction may have an impact on the number of positive LNs detected and may have important prognostic significance.^{121,122} However, the prognostic value of these positive LNs, which otherwise would not be detected, remains controversial. In a recent review of 16 studies with survival data, Sirop et al.¹²³ found only 8 papers that reported definitely poorer outcomes, whereas the remainder were either equivocal in their conclusions or demonstrated no influence on outcome at all. Jeffers et al.¹²⁴ evaluated LNs from 77 patients who were found to have negative LNs by routine examination with immunocytochemical staining for cytokeratin AE1:AE3. Nineteen patients (25%) were found to have immunohistochemical evidence of micrometastases; however, there was no difference in survival between the microscopically positive and negative patients. A larger trial by Faerden et al.,¹²⁵ on the other hand, did demonstrate adverse prognostic impact. In this study, 39 of 126 patients with stage I/II colon cancer were noted to have micrometastases or isolated tumor cells (MM/ITC+) on IHC staining. Prospective median 5-year follow-up of MM/ITC+ compared to MM/ITC- patients revealed recurrence rates of 23% versus 7% ($p = 0.010$) and 5-year DFS of 75% versus 93% ($p = 0.012$), respectively.¹²⁵ If micrometastases are reported, the methodology by which they are detected should be specified, as it is likely that differences in reliability and reproducibility of different techniques will emerge. Although the actual TNM staging is not altered by the presence of micrometastases, many clinicians choose to regard the presence of such a finding as a poor prognostic variable in their consideration of adjuvant treatment.

Sentinel Node Analysis

Sentinel node analysis is an approach that has received attention in the management of cutaneous melanoma and breast cancer.^{126,127} This technique has been proposed as a means of increasing the yield and the diagnostic information for colon cancer.^{91,92} The technique for sentinel node mapping and biopsy for colon cancer has been described by Saha et al.¹²⁸ Unlike sentinel node approaches for melanoma and breast, where the goal is to potentially limit the extent of an unnecessary formal dissection of a node basin, the goal of the sentinel node in colon cancer is to focus the pathologic analysis on fewer nodes so a more extensive study can be performed. The same extent of node dissection is performed regardless of the sentinel node procedure. The initial studies of sentinel node biopsy demonstrated it was technically feasible, with accuracy rates >80% and upstaging in 15.4% of patients according to a recent prospective trial.¹²⁹⁻¹³¹ In addition, Saha et al.¹³² suggest that sentinel LN mapping may not just improve staging accuracy but influence the extent of nodal dissection as well. In this study, sentinel LN mapping detected aberrant lymphatic drainage in 22%, which in turn led to a change in operation (i.e., more extensive resection). In two patients, the aberrant sentinel nodes were the only positive nodes identified.¹³² However, not all subsequent studies have shown positive results. False-negative rates as high as 60% have been reported, and some studies have failed to demonstrate any change in the stage determination of the lesion.¹³³ Based on the available data, two conclusions can be reached. First, from a technical standpoint, sentinel node dissection at the time of a colon resection can be performed and the sentinel node accurately identified. Second, the utility of this technique has not yet been established and further large-scale trials are required to establish its role in the staging of patients with CRC.

Blood or Lymphatic Vessel Invasion

Although there have been conflicting reports in the literature, the CAP consensus statement gave blood and lymphatic vessel invasion category I status, indicating that the preponderance of evidence

strongly supports the reliability of these findings as indicators of poorer prognosis.¹⁰⁹ Unfortunately, considerable heterogeneity exists in the methodology for examining and reporting of vessel involvement. The finding of vessel involvement increases with the number of sections examined, and differentiation of postcapillary venules from lymphatics is often not possible. These aspects can make interpretation of some older data on this topic potentially problematic. Current recommendations are that at least three blocks of tumor (optimally five or more) each have a single section examined using hematoxylin and eosin stain to look for tumor invasion of vessels. Vessels not definitively interpreted as venules or lymphatics should be reported as angiolymphatic vessels.

Histologic Type

Several histologic types of CRC carry specific independent prognostic significance. Signet ring carcinomas are characterized by >50% of cells demonstrating the “signet ring” morphology in which intracellular mucin accumulation displaces the nuclei and cytoplasm toward the cellular periphery. This histology carries an adverse prognosis.^{134,135} The prognostic significance of the finding of mucinous (>50% mucinous) carcinoma remains controversial. Although some reports list mucinous type as an adverse histology, this has not been consistently demonstrated. Most findings of adverse prognosis with mucinous histology are based on univariate analyses. The one finding in a multivariate analysis of a poor prognostic outcome with mucinous tumors was based on a study of tumors presenting with obstruction, a presentation that is in itself high risk. Some reports have lumped mucinous and signet cell tumors together and found this to be a negative prognostic factor; however, this may simply reflect the negative impact of the signet cell tumors, and its meaning regarding the risk of a mucinous histology is unclear. Small cell (extrapulmonary oat cell) tumors are high-grade neuroendocrine tumors with clearly adverse prognostic features. The prognostic significance of focal neuroendocrine differentiation is, however, unclear (CAP category III). Most data indicate that extensive neuroendocrine differentiation is associated with a poorer prognosis.¹³⁶ Medullary carcinoma is a subtype characterized by an absence of glands and distinctive growth pattern that previously would have been classified as undifferentiated. It is typically infiltrated with lymphocytes. This histologic subtype is tightly associated with MSI-H and carries a more favorable prognosis.¹³⁷ Histologic types other than signet ring, small cell, and medullary carcinomas are routinely designated in the pathology report; however, the majority of these other histologic types carry no established independent prognostic significance.

Microsatellite Instability

As discussed earlier in this chapter, there are two distinct mutational pathways that can give rise to CRC: the MSI pathway or the chromosomal instability pathway. Microsatellites are sections of DNA in which a short sequence of nucleotides (most commonly a dinucleotide) is repeated multiple times.¹³⁸ MSI is a situation in which a microsatellite has gained or lost repeat units and so has undergone a change in length, resulting in frame shift mutations or base-pair substitutions. Approximately 15% of CRCs display these mutations. This form of genetic destabilization is typically associated with defective DNA mismatch repair function. Studies of HNPCC tumor specimens demonstrated mutations in mismatch repair genes such as *MLH1* and *MSH2*. These genes encode proteins that repair nucleotide mismatches. The phenotype of tumors with this defect is termed the MSI-H–instability phenotype.

The majority (approximately 85%) of patients with CRC have cancers characteristic of the chromosomal instability pathway, typically having genetic alterations involving LOH, chromosomal amplifications, and chromosomal translocations. These are known as the microsatellite-stable (MSS) tumors. MSI-H tumors have a number of different features relative to low MSI (MSI-L)

or MSS colorectal tumors.^{139,140} MSI-L and MSS tumors tend to behave and present similarly. MSI-H tumors are more frequently right-sided, high grade, and mucinous type.^{24,141} They are characteristically associated with increased peritumoral lymphocytic infiltration and are characteristically diploid, whereas MSS tumors are more likely to be aneuploid.^{142,143} MSI-H CRCs are more likely to have a larger primary at the time of diagnosis but are more likely to be node negative. Patients with MSI-H CRCs have a better long-term prognosis than stage-matched patients with cancers exhibiting MSS.¹⁴⁴

Watanabe et al.¹⁴⁵ evaluated MSI status as well as allelic loss from chromosomes 18q, 17b, and 8p, as well as cellular levels of p53 and p21^{waf1/cip1} proteins as potential prognostic markers. Tumors were analyzed from 460 stage III and high-risk stage II patients who had been treated with 5-FU–based adjuvant therapy. A total of 62 of 298 tumors evaluated for MSI status (21%) were found to be MSI-H. Of the MSI-H tumors, 38 (61%) had a mutation of the gene for type II receptor of transforming growth factor (TGF)- β 1. In this analysis, MSI-H was a favorable prognostic indicator for 5-year DFS ($p = 0.02$) and trended toward being a favorable independent prognostic indicator, but did not reach statistical significance for overall survival ($p = 0.20$). However, the 5-year survival among patients with MSI-H was 74% in the presence of a mutated gene for the type II receptor of TGF- β 1 and 46% in patients whose tumors lacked this mutation (RR = 2.90; 95% CI = 1.14 to 7.34; $p = 0.04$). MSI-H cells are relatively resistant to 5-FU in vitro.¹⁴⁶ All of the patients in Watanabe et al.’s¹⁴⁵ analysis received 5-FU–based chemotherapy. The TGF- β 1 pathway inhibits tumor proliferation by causing a late G₁ cell cycle arrest. Therefore, a mutated and presumably nonfunctional TGF- β 1 gene could favor increased proliferation, which would be anticipated to confer increased susceptibility to cytotoxic chemotherapy. A recent evaluation of the prognostic significance of MSI in the N0147 adjuvant trial¹⁴⁷ demonstrated a more nuanced result. When looking at the colon overall, MSI was not found to be predictive. However, when divided by side, MSI was found to carry a favorable prognosis for right-sided colon lesions, but was a negative prognostic factor in left-sided colon lesions. The reasons for this difference is not clear; however, the different embryologic origins of the left and right colon may play a role in these observations.

BRAF

BRAF mutation, present in 10% to 20% of CRCs, is linked to a subset of MSI-H tumors that are sporadic and generally have poorer prognosis. Ogino et al.¹⁴⁸ confirmed this relationship in comparative analysis of 506 stage III patients enrolled in the Cancer and Leukemia Group B (CALGB) 89803 trial. BRAF-mutated patients had significantly worse overall survival (HR = 1.66) compared to wild-type, a finding that was most pronounced in the setting of MSS.¹⁴⁸ In a follow-up study, Lochhead et al.¹⁴⁹ also identified combined BRAF/MSI status as a powerful prognosticator and recommends stratification of all patients into poor (MSS/BRAF mutant), intermediate (MSS/BRAF wild-type), and favorable (MSI-H/BRAF wild-type) groups in order better inform treatment strategies. Douillard et al.¹⁵⁰ confirmed BRAF mutation to be a poor prognostic factor in patients with stage IV disease as well.

Allelic Loss of 18q (DCC Gene Loss)

Allelic LOH that involves chromosome 18q occurs in half or more of all CRCs. Allelic loss of 18q typically involves the *DCC* gene; however, other genes in this region, such as *Smad2* and *Smad4*, may also be relevant to CRC development. *DCC* expression is greatly reduced or absent in many colorectal carcinomas, and loss of *DCC* is associated with metastasis and an adverse prognosis.¹⁵¹ The specific product of the *DCC* gene has been shown to be the netrin-1 receptor. In the nonpathologic state, this receptor guides the migration of neuronal axons. *DCC* induces apoptosis in the absence of netrin-1 binding. *DCC* is cleaved by caspase, and mutation of the site at

TABLE 57.7**Loss of Heterozygosity (Allelic Loss) at 18q and Prognosis in Patients with Stage III Colon Cancer**

Allelic Status of 18q	No. of Patients	Five-Y Survival (%)	P Value
No loss	112	69	0.005
Loss	109	50	

From Watanabe T, Wu TT, Catalano PJ, et al. Molecular predictors of survival after adjuvant chemotherapy for colon cancer. *N Engl J Med* 2001;344:1196–1206.

which caspase 3 cleaves DCC suppresses the proapoptotic effect of DCC completely. Binding of netrin-1 to DCC blocks apoptosis.¹⁵² Loss of DCC as a result of allelic loss in 18q could therefore be anticipated to impair apoptosis, thereby resulting in greater resistance to chemotherapy. This hypothesized mechanism of action of 18q LOH is attractive; however, it should be emphasized that it is not at all clear to what extent DCC is the active moiety in the setting of 18q allelic loss. Watanabe et al.¹⁴⁵ evaluated allelic loss from chromosome 18q as a potential prognostic indicator in archived specimens of tumors from patients who were treated in one of two national Intergroup adjuvant trials (INT 0035 or INT 0089). MSI status was also evaluated, as were 17p, 8p, and cellular levels of p53 and p21^{waf1/cip1} proteins. Tumors were analyzed from 460 stage III and high-risk stage II patients who had been treated with 5-FU–based adjuvant therapy. Allelic loss of 18q was present in 155 of 319 cancers (49%). Allelic loss in 18q was highly prognostically significant in this analysis (Table 57.7). In the stage III patients with allelic loss of 18q, 5-year overall survival was 50%, while in those with retained 18q alleles, 5-year survival was 69% ($p = 0.005$). Other markers evaluated in this analysis were not shown to be prognostically significant.

Host Lymphoid Response

Lymphocytic infiltration has been identified as a favorable prognostic indicator. Whether this is a truly independent predictor of outcome is not clear, however, as this finding is tightly associated with MSI-H, a favorable prognostic factor. Along these lines, the prognostic value of neutrophil-to-lymphocyte ratio has also been recently evaluated. Chiang et al.¹⁵³ found that elevated preoperative neutrophil-to-lymphocyte ratio (>3) was associated with significantly worse DFS in stage I to III colon but not rectal cancers on multivariate analysis. In another study, neutrophil-to-lymphocyte ratio (>5) was also found to be an independent risk factor for recurrence. While the direct impact of this parameter is difficult to explain, the authors of the first study postulate that it may represent a measure of innate-to-adaptive immunity under stress with relative lymphopenia, as a marker of depressed cell-mediated immunity, conferring survival disadvantage.^{153,154}

Tumor Border Configuration

The configuration of the tumor border (infiltrating versus pushing border) has been shown to have independent prognostic significance. An infiltrating border, characterized by an irregular, infiltrating pattern at the tumor edge (also known as focal dedifferentiation or tumor budding), has been shown in multivariate analyses to portend a poorer prognosis than tumors with smooth, pushing borders.

Carcinoembryonic Antigen

An elevated preoperative CEA is a poor prognostic factor for cancer recurrence. Although there is variability in the available data regarding the level that denotes a prognostic cutoff, a preoperative CEA level >5 ng/ml is considered a category I poor prognostic indicator

by the CAP consensus panel.¹⁰⁹ Patients in whom the elevated CEA fails to normalize after a potentially curative operation are at particularly high risk. Several authors have presented evidence that indicates that CEA is an independent prognostic factor. In a report of 572 patients who underwent curative resection for node-negative colon cancer, the preoperative CEA level and the stage of disease predicted survival by both univariate and multivariate analyses.¹⁵⁵ Given the prognostic significance of the preoperative CEA, it is reasonable to recommend that all patients who undergo operation for CRC have a serum CEA drawn prior to operation.

No other serum markers have been demonstrated to be reliably prognostic or predictive in CRC. Cancer antigen (CA) 19-9, a factor that has become widely used for pancreas cancer, has no role at this time in the routine management of CRC.

Obstruction and Perforation

Carcinoma of the colon that is complicated by obstruction or perforation has been recognized as having a poorer prognosis. Data obtained from 1,021 patients with Dukes stage B and C CRC, who were entered into randomized clinical trials of the National Surgical Adjuvant Breast and Bowel Project (NSABP) showed that the presence of bowel obstruction strongly influenced the outcome. The effect of bowel obstruction was more pronounced when the obstruction was located in the right colon. The larger-sized tumor needed to block the ascending colon completely might allow a longer time for these tumors to grow and spread when compared with tumors located in the descending colon.

A review of the Massachusetts General Hospital records compared patients who presented with obstruction or perforation with a control group who underwent curative resection. The actuarial 5-year survival rate seen in patients who presented with obstruction was 31%, in contrast to 59% in historical controls. For patients with localized perforation, the 5-year actuarial survival rate was 44%. The Gastrointestinal Tumor Study Group (GITSG) multivariate analysis concluded that obstruction was an important indicator of prognosis, independent of Dukes stage. Bowel perforation was a poor prognostic factor only for DFS.

Category III Factors

Multiple factors, while of investigational interest, are at this time not appropriate for routine clinical use and have so been designated as category III (defined as not sufficiently studied to prove their prognostic value) by the CAP consensus panel. These include DNA content, or ploidy, and proliferation indices. Also included in category III are all molecular markers other than MSI and 18q deletions, such as thymidylate synthase (TS), dihydropyrimidine dehydrogenase (DPD), and p53 mutational status. Perineural invasion, microvessel density, tumor cell-associated proteins or carbohydrates, peritumoral fibrosis, peritumoral inflammatory response, and focal neuroendocrine differentiation are also category III. The area of molecular prognostic markers is one of particular activity, however, and it is anticipated that clinical trials that are now ongoing will shed light on these important areas.

Perineural Invasion

The ability of CRCs to invade perineural spaces as far as 10 cm from the primary tumor has long been described. Early reports suggest an increased disease recurrence rate and worse 5-year survival. Multivariate analyses have failed to show the prognostic significance of this finding. The CAP consensus panel classified perineural invasion as category III (insufficient evidence of determine prognostic significance).

Tumor Size and Configuration

Studies have consistently shown that both the size and configuration of the primary tumor in CRC do not carry prognostic

significance (CAP category IV). In a review of 391 patients, the mean diameter of Dukes stage B2 tumors was actually greater than the mean diameter of stage C2 tumors ($p < 0.001$) and D tumors ($p < 0.05$). The size of the primary tumor showed no relationship to 5-year adjusted survival. These results were confirmed by the NSABP experience.¹⁵⁶ Tumor configuration is described as exophytic (fungating), endophytic (ulcerative), diffusely infiltrative (linitis plastica), or annular. The vast majority of studies have failed to show any of these configurations to have consistent independent prognostic significance. Linitis plastica has been related to a poor prognosis; however, this may be due to the signet cell and other high-grade features of the tumors that are typically associated with this morphology.

Hemorrhage or Rectal Bleeding

It has been speculated that tumors that present with bleeding might be found earlier and therefore might be associated with a better prognosis. This has not been confirmed by data. In the GITSG multivariate analysis, the presence of melena or rectal bleeding showed a trend as a prognostic factor for prolonged survival but failed to reach statistical significance ($p = 0.08$). One large study found bleeding to be a favorable prognostic indicator on univariate analysis; however, this finding disappeared on multivariate analysis. Bleeding at presentation does not appear to carry any significance.

Primary Tumor Location

Large retrospective reviews of data from the NSABP suggest that right-sided colon cancers carry a worse prognosis than left-sided ones. However, poorer prognosis for patients with disease in the left colon has also been reported. Several investigators report no difference based on the location of the primary tumor. The large GITSG colon cancer experience showed that tumor location (left, right, and rectosigmoid or sigmoid) was of low prognostic value. A recent analysis of SEER-Medicare data by Weiss et al.¹⁵⁷ provides additionally ambiguous results. Of 53,801 patients, 67% had right-sided colon cancer and were more likely to be older, women, and diagnosed with more advanced stage and with more poorly differentiated tumors. However, on multivariate analysis, there was no significant difference in mortality for all stages combined or for stage I. Compared to left-sided lesions, right-sided cancers were associated with a lower mortality within the stage II subgroup (HR = 0.92; $p = 0.001$) but higher mortality within stage III (HR = 1.12; $p = 0.001$). Critics of this report point out that a less aggressive treatment approach was likely employed in this older study population, as at least 40% of stage III cases did not receive adjuvant therapy and nearly half underwent inadequate LN harvest. Regardless, these results further dispel the notion of a straightforward relationship between tumor location and mortality.¹⁵⁷

Body Mass Index

While obesity is known to be a risk factor for the development of colon cancer, the prognostic impact of body mass index on long-term outcomes is controversial. In a cohort study conducted within a large randomized trial of 3,759 patients with high-risk stage II or III colon cancer (INT-0089), obese women had significantly worse overall mortality (HR = 1.34; 95% CI = 1.07 to 1.67); however, this finding was not apparent in men.¹⁵⁸ Sinicrope et al.¹⁵⁹ found the opposite gender correlation using the ACCENT database, a pooled resource of 25,291 participants in national and international adjuvant chemotherapy trials. On multivariate analysis, with a median follow-up of 7.8 years, obese and underweight men, but not women, had significantly poorer survival compared to overweight and normal weight patients.¹⁵⁹ And in another prospective cohort of 913 patients with stage II and III colon cancer, Alipour et al.¹⁶⁰ found no association between obesity (as measured by either body mass index or body surface area) and oncologic outcomes. Evidently, this topic warrants further study before any conclusions can be drawn.¹⁶⁰

Diabetes Mellitus

The influence of diabetes mellitus on outcome is also unclear. In the INT-0089 cohort, diabetes conferred a strong disadvantage with affected patients experiencing a significantly worse DFS (48% versus 59%; $p < 0.0001$), overall survival (57% versus 66%; $p < 0.0001$), and recurrence-free survival (56% versus 64%; $p = 0.012$) at 5 years. Median survival for diabetics was 6 years, whereas for nondiabetics it was 11.3 years.¹⁵⁸ Other reports, however, have generated less consistent results. Among 2,278 subjects from the Cancer Prevention Study-II Nutrition Cohort, patients with CRC and type 2 diabetes were at higher risk of all-cause mortality (ACM; RR = 1.53), but only those without insulin use were at higher risk for CRC-specific mortality. These results are in line with previous evidence that hyperinsulinemia (as in poorly controlled diabetes) plays an important role in tumorigenesis and metastasis of CRC.¹⁶¹ Another population-based study did not find any such an association in 6,974 patients with colon cancer. Disease-specific mortality was only significantly increased for patients with rectal cancer ($n = 3,888$, 10% of whom were diabetic; HR = 1.30). While hyperinsulinemia is again implicated, the authors call for additional study to clarify specific pathways responsible for these rectum-specific findings.¹⁶²

Gender

Female sex has generally been considered a favorable prognostic factor, but data is limited and inconclusive. In the first study to examine the impact of gender in the era of oxaliplatin-based therapy, Cheung et al.¹⁶³ performed a prospectively planned, pooled analysis of 33,345 patients participating in the ACCENT database of randomized trials. The authors found a significant but very modest survival advantage for women with early stage disease that persisted across all ages, stages, and types of adjuvant therapy. Sex was not a predictive factor for treatment efficacy, however, suggesting that chemotherapy regimens should be not be altered based on this parameter.¹⁶³

Smoking

As discussed earlier, prolonged cigarette smoking appears to be a moderate risk factor for CRC with continued effect even after smoking cessation. Increasing evidence indicates that this association differs not just by tumor site but also by molecular features, such as the presence of MSI-H and BRAF mutations, which cumulatively seem to confer the strongest risk. Impact on survival has now also been reported in a recent study analyzing data from a large multicenter randomized adjuvant chemotherapy trial (N0147). The authors found that smokers experienced significantly shorter 3-year DFS (74% versus 70%; HR = 1.21) that was most evident in BRAF wild-type and KRAS-mutated tumors.¹⁶⁴

Blood Transfusions

Considerable controversy has surrounded the question of an association between perioperative blood transfusions and the recurrence rate of CRC. Some investigators have reported worse DFS in patients who require transfusions. By multivariate analysis in a large prospective study, however, no negative influence of transfusion on survival could be detected, and it does not appear that perioperative blood transfusions carry negative prognostic value. A retrospective analysis evaluating 1,051 patients treated with curative surgery for stage II or III colorectal adenocarcinoma at the Mayo Clinic demonstrated that the use of blood components probably had no impact on disease recurrence, and the documented adverse impact of transfusions is more likely due to other variables or to the underlying illness necessitating the transfusion.¹⁶⁵

Oncogenes and Molecular Markers

Oncogenes and molecular markers are discussed extensively in another chapter. At present, none of the markers under investigation

has achieved adequate validity to permit routine clinical use. However, the study of molecular markers continues to progress and continues to advance the understanding of the development and treatment of CRC. TS continues to be a major area of investigation. Data are conflicting on its prognostic significance; however, preliminary studies suggest that high TS levels may be predictive for resistance to 5-FU-based therapies.¹⁶⁶ At present, there is no role for TS determinations in routine clinical practice. The *p53* gene located on chromosome 17p is a well-known tumor suppressor gene. The abnormal *p53* appears to be a late phenomenon in colorectal carcinogenesis. This mutation may allow the growing tumor with multiple genetic alterations to evade cell cycle arrest and apoptosis. In a retrospective review of 141 patients with resected stage II and III colon carcinoma, a *p53* mutation increased the risk of death by 2.82 times in patients with stage II disease and by 2.39 times in patients with stage III colon carcinoma. The Southwest Oncology Group assessed the prognostic value of *p53* in 66 patients with stage II and 163 stage III colon cancer. *p53* expression was found in 63% of cancers and was associated with favorable survival in stage III but not stage II disease. Seven-year survival with stage III disease was 56% with *p53* expression versus 43% with no *p53* expression ($p = 0.012$).¹⁶⁷ Overall, the data are conflicting on the utility of *p53* as a prognostic variable, and it does not have a use at this time in standard practice.

Epidermal growth factor receptor (EGFR) is an important molecular target for antibody-based therapy in various cancer types and is ubiquitous in colonic tissue. The prognostic impact of this biomarker was recently addressed in a meta-analysis demonstrating worse postoperative survival in patients with high compared to low EGFR expression (HR = 2.34).¹⁶⁸

Genetic Polymorphisms

Extensive preliminary work is indicating that genetic polymorphisms can potentially have important predictive implications in terms of both efficacy and toxicity with chemotherapy. For example, the UGT1A1 polymorphism has been correlated with CPT-11 toxicity, and TS and XRCC1 polymorphisms may predict efficacy for oxaliplatin or 5-FU combinations.¹⁶⁹ Although a commercial assay is currently available for measurement of UGT1A1 polymorphisms, it is not, at this time, clear how, or if, this assay should be used in routine practice. Currently, there are no specific guidelines for dose modifications on the basis of UGT1A1 polymorphism, and the 7/7 mutation, associated with higher toxicity, has also been associated with greater antitumor activity. These approaches will require considerable more validation and exploration before they can be considered for standard management.¹⁷⁰

APPROACHES TO SURGICAL RESECTION OF COLON CANCER

The management of colon cancer is best understood as a multimodality approach tailored to the stage of disease. However, there are certain basic tenets of surgical management for the resection of the primary lesion that can be applied across various pathologic stages. Therefore, in order to provide a clear description of these techniques, they will first be described based on the type of surgical resection. These procedures will then be referred to throughout the discussion of stage-specific treatment.

Colonoscopic Resection of Polyps

Many lesions of the colon are first detected during endoscopic procedures. These lesions can range from small hyperplastic polyps to large fungating invasive carcinomas. The appearance of these lesions often indicates their relative potential for malignancy. However, the only definitive way to make a diagnosis is through a pathologic examination of the tissue. Therefore, the goal of a

colonoscopic biopsy or resection is to, whenever feasible, remove the lesion in its entirety and preserve a tissue architecture in order to achieve both a therapeutic resection and an accurate pathologic diagnosis. Various techniques can be employed for the removal of lesions in the colon depending on their size and location. Biopsy forceps and snares are the two most commonly employed instruments used during a colonoscopy. These devices are fashioned from flexible coated wires that can conform to the shape of the colonoscope and can also conduct electrical current in order to achieve coagulation and hemostasis.

Bleeding and perforation, while uncommon, are seen at an increased frequency during a therapeutic as opposed to a diagnostic colonoscopy.^{171,172} Small polypoid lesions (up to 5 to 8 mm) that are found during the course of a colonoscopic examination can often be removed in their entirety along with a small amount of normal mucosa using a biopsy forceps. Bleeding is usually minimal but can be controlled by electrocautery if persistent. Larger well-pedunculated polyps can often be removed using a technique employing a snare and electrocautery. The snare is placed over the polypoid lesion and cinched down at the base of the polyp. Once tightened, an electrical current is applied and the polyp is resected. If the lesions are too large to be retrieved through the working port of the colonoscope, they can be held in place with a snare just beyond the tip of the colonoscope where they can be kept in view and withdrawn with the scope from the patient. It is important, when sending these specimens to pathology, to properly orient the polyp so as to indicate the base where the resection took place as well as the other positions of the lesion. This will allow the pathologist to provide important information as to the margin status for the resection. Carcinoma in situ as well as stage I invasive carcinomas found in a well-pedunculated polyp can be treated with colonoscopic resection, as described previously, and no further surgical management is needed as long as there is a negative margin >2 mm and the tumor is well-differentiated without lymphovascular invasion or extension of malignant cells beyond the stalk (Haggitt levels 1 to 3).¹⁷³ If these criteria are not met, further therapy is required. It is for this reason that it is often helpful to mark the site of the polyp resection with an agent that will leave a "tattoo" to guide additional intervention.

Larger lesions with a broad base or sessile lesions are best biopsied to make a diagnosis rather than resected using the colonoscope. The risk of perforation or inadequate resection margins is greatly increased with broad-based and sessile lesions. Multiple biopsies should be taken in order to determine whether the lesion harbors an invasive cancer, and further resection decisions are made based on the pathologic findings. In cases where there is low suspicion for malignancy, an endoscopic mucosal or submucosal resection may be attempted, usually by a gastroenterologist with advanced interventional endoscopic expertise. However, if such a lesion is left behind, it is of critical importance to note the position of the lesion in order that it might be more easily found if a subsequent procedure is required. In addition to determining the depth of insertion of the scope, which can be highly inaccurate with flexible instruments, other landmarks including the appendiceal orifice or ileocecal valve in the cecum and the liver/splenic shadows at the flexures should be noted. The most important step however is to properly mark the polyp site with 1 ml of tattoo injected submucosally in each of four quadrants for definitive intra- and extraluminal recognition at a later date.¹⁷⁴

For lesions that cannot be resected through the scope or are found to be invasive carcinomas that are sessile or broad based, a variety of surgical resections can be employed depending on the position of the lesion and its T stage. It is important to keep in mind, however, that the formal staging of the lesion does not occur until after the resection is completed; therefore, if there is any suspicion of an invasive carcinoma being present, a definitive oncologic resection should be performed.¹⁷⁵

Bowel Preparation

An important part of the preoperative regimen for a colon resection is the proper cleansing of the bowel in order to reduce the risk of postoperative complications as well as to allow for easier visualization during the procedure, particularly with the laparoscopic approach. A variety of regimens have been described, and there are many that have demonstrated efficacy.^{176,177} Although there are several choices described in the literature, the basic components of a bowel preparation are a mechanical cleansing of the bowel using a cathartic or volume-displacing agent and appropriate antibiotic prophylaxis.^{178,179} Recently, some studies have suggested that mechanical bowel preparation may be unnecessary; however, this remains controversial.^{180,181}

For rectal and low sigmoid tumors, a number of surgeons also perform distal rectal washout prior to resection, with the professed intention of eliminating exfoliated intraluminal cancer cells that may increase local recurrence risk. There has been little evidence to support this theory, and washout has not been routinely recommended as standard practice. However, a recent meta-analysis of nine studies and 5,395 patients is the first to demonstrate a significant benefit to this maneuver with a nearly two-fold reduction in local recurrence rates (5.79% versus 10.05%; $p < 0.00001$). While the lack of randomized controlled trials limits the strength of this data, the authors conclude that distal washout should be reconsidered in all patients given the minimal cost, time, and risk it entails.¹⁸²

Anatomic Resection

For invasive carcinomas of the colon, stages I through III, the surgical approach will be dictated by the size and location of lesions in the colon.^{183,184} The location will determine what region of bowel is removed, and the extent of its resection is dictated by its vascular and lymphatic supply.

Resection of the Right Colon

Lesions in the cecum and ascending colon are managed with a right hemicolectomy (Fig. 57.3A,B). The right colon is mobilized from the retroperitoneum by incising its retroperitoneal attachments, taking care to avoid injury to the ureter, inferior vena cava, duodenum, and gonadal vessels. The colon is mobilized from the ileum to the transverse colon, taking care at the hepatic flexure not to injure the gallbladder or duodenum. The ileocolic, right colic, and right branch of middle colic vessels are then ligated and divided. A proximal ligation in order to allow for the removal of colonic mesentery along with LNs is performed for staging purposes. Once the vascular supply is divided and the intervening mesenteric tissue ligated and divided, attention can be addressed to the resection of the colonic tissue.

There are a variety of techniques for dividing the colon. This can be done between clamps using scalpel or using a variety of stapling devices. One method would be to use a linear GI anastigmatic stapler. After making a small hole just below the colonic wall though the mesentery at the point chosen for resection, the stapler can be positioned across the colon and fired, thus dividing the tissue. This is then repeated across the ileum just proximal to the ileocecal valve. Once divided, all remaining mesenteric tissue is carefully ligated and divided, and the colonic specimen can be removed. Although a no-touch “technique” has been advocated in the past, studies have demonstrated that this has no influence on recurrence or seeding of distant disease.¹⁸⁵ Once the right colon has been removed, intestinal continuity can be re-established by creating an anastomosis between the terminal ileum and the remaining transverse colon using either a hand-sewn or stapled technique.

Resection of the Transverse Colon

For lesions located in the transverse colon, a variety of approaches can be undertaken. Those lesions that are proximal and

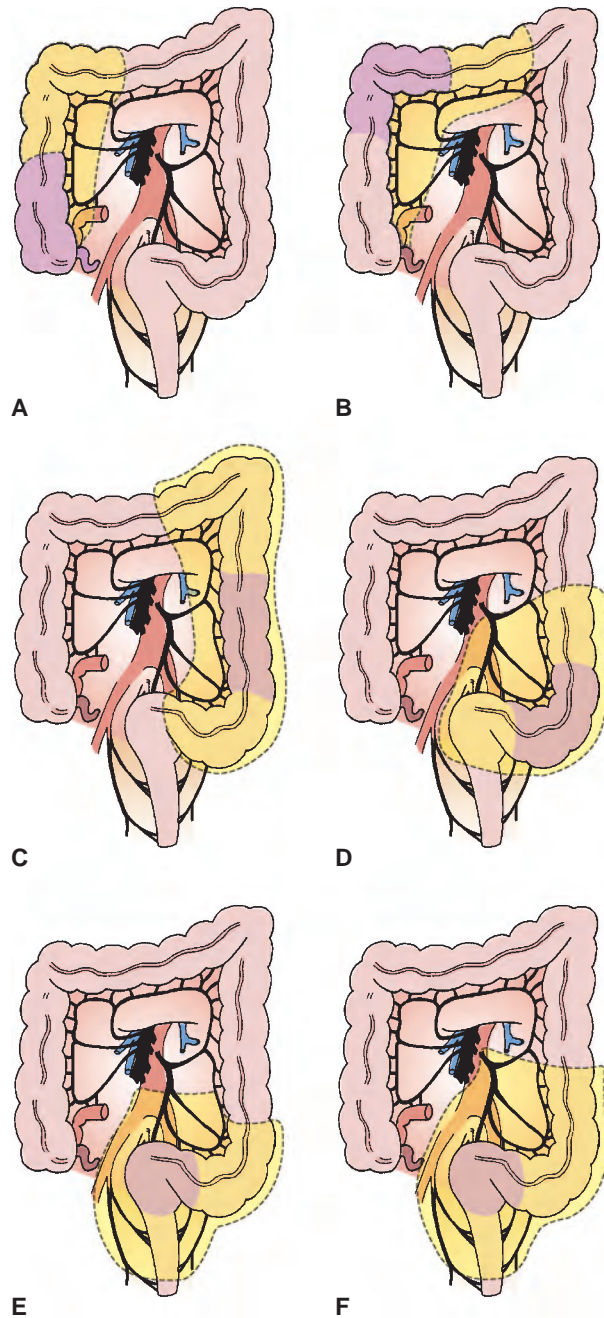

Figure 57.3 (A) Surgical resection for a cecal or ascending colon cancer. (B) Surgical resection for a cancer at the hepatic flexure. (C) Surgical resection for a descending colon cancer. (D) Preferred surgical procedure for cancer of the middle and proximal sigmoid colon. In poor-risk patients, the inferior mesenteric artery and the left colic artery may be preserved. (E) Surgical resection for cancer of the rectosigmoid. (F) A more radical surgical resection for cancer of the rectosigmoid.

near the hepatic flexure can be resected with an extended right hemicolectomy. This extension should encompass up to and include the middle colic vessel. The advantage of such a resection over a true transverse colectomy is that the anastomosis performed to restore intestinal continuity involves an anastomosis between the ileum and the remaining colon. Due to the improved blood supply delivered by the small bowel mesentery, there is a decreased risk of an anastomotic leak in an ileocolic as opposed to a colocolic anastomosis.¹⁷⁵ Likewise, a lesion in the distal transverse colon can be resected with an extended left hemicolectomy, which

will be described in more detail in the following section. For those lesions that are in the midportion of the transverse colon, however, a transverse colectomy can be performed. This procedure requires mobilization of the right colon in order to allow this tissue to be brought over for an anastomosis following the resection.

The omentum is divided from the greater curvature of the stomach up to and including its attachments at the splenic helium. The omentum can often be a source of micrometastatic disease and therefore its resection at the time a transverse colectomy is indicated. After dividing the omentum and mobilizing the right and transverse colon up to and including the splenic flexure, the middle colic artery is ligated at its trunk and smaller vessels from the right and left colic artery branches can be ligated and divided as required. A linear stapler can once again be used to divide the colonic tissue, and then the mobilized right colon can be anastomosed to the descending colon in an end-to-end fashion using a hand-sewn anastomosis or using a side-to-side stapled technique. Depending on the size of the transverse colon, however, it is often safer and easier to resect the right and transverse colon and connect the ileum to the descending colon. This allows enough colonic reserve for water absorption and normal bowel movements.

Resection of the Descending and Sigmoid Colon

For lesions in the proximal descending colon, the splenic flexure is mobilized and the left colic artery can be ligated and divided with the portion of colon removed by mobilizing the splenic flexure and dividing the omentum (Fig. 57.3C,D). The transverse colon can be brought over to the region of the sigmoid colon for anastomosis. For lesions in the midportion of the descending colon, a left hemicolectomy can be performed, taking care to ligate the left colic vessel along with some sigmoidal branches and taking an adequate portion of mesentery for staging purposes.

For lesions that involve the sigmoid colon, a sigmoid colectomy can be performed with margins of resection on either side of the lesion. The descending colon is mobilized (together with the splenic flexure as needed) and connected to the rectum using either a hand-sewn anastomosis or stapling device. The mesentery can be divided either at the level of the sigmoidal branches with preservation of the left colic artery or at the origin of the inferior mesenteric pedicle (Fig. 57.3E,F). While the latter approach is preferred by some to achieve greater mobilization and higher lymph node counts, neither this nor a more extensive left hemicolectomy has resulted in improved survival.

The approaches to the resection of lesions below the peritoneal reflection will be discussed in the chapter on rectal cancer.

Total Abdominal Colectomy

For patients with ulcerative colitis or familial polyposis syndrome who either have evidence of invasive carcinoma or are at significant risk for the development of invasive carcinoma, a total abdominal colectomy may be required. This can be performed by mobilization of the right colon, transverse colon along the omentum, taking the omentum as part of the resection, the hepatic and splenic flexures, as well as the complete mobilization of the descending colon down to the peritoneal reflection. Ligation of the ileocolic, right colic, middle colic, left colic, and sigmoid branches will allow for removal of the colon down to the peritoneal reflection. For ulcerative colitis and familial polyposis syndromes without evidence of carcinoma below the peritoneal reflection, the operation can be terminated at this point with ileorectal anastomoses and careful surveillance of the remaining rectum via proctoscopy. However, in order to remove all tissue at risk for further lesions, a total proctocolectomy is often advocated.^{186,187} Although this procedure can be performed as an abdominal perineal resection with a permanent end ileostomy, most surgeons now advocate one of many continent pull-through procedures in order to preserve fecal continence in a patient population that is often very young. Such

procedures provide very good control of continence and a relatively normal lifestyle.¹⁸⁸

SURGICAL MANAGEMENT OF COMPLICATIONS FROM PRIMARY COLON CANCER

Patients with primary lesions of the colon can present with obstruction, bleeding, and perforation. The surgical management of these patients can be complex, requiring intraoperative decisions tailored to the situation encountered. Blood per rectum can be one of the most frightening experiences for patient and physician alike. Bleeding from a CRC can occur anywhere from the cecum to the distal rectum. Although bleeding can be temporized with endoscopic fulguration and the patient supported with transfusion, definitive management of the lesion with either surgery or radiation therapy will ultimately be required. Other maneuvers such as angiographic embolization may provide only a temporary solution. Fortunately, life-threatening hemorrhage due to a colon cancer primary is a rare occurrence. More often, these lesions lead to a chronic blood loss, resulting in anemia.

Colonic obstruction due to a primary tumor is not uncommon. Obstructing colon lesions present several important issues. First, the acute obstruction must be managed. Ideally, an exploration with resection of the tumor and primary anastomosis with or without a diversion is ideal. However, given the fact that the operation will be performed on unprepared bowel and the patient's physical condition may be less than optimal, resection without an anastomosis and an end colostomy should be considered. In some instances, the obstructing lesion may present significant technical hurdles for resection in the setting of an acutely dehydrated and ill patient. In these circumstances, a decompression maneuver that can be performed rapidly and with minimal morbidity such as a transverse loop colostomy or a colostomy and mucous fistula can be performed to temporize the situation and allow the patient to be prepared and resuscitated adequately for a definitive resection at a second exploration.

Bypass operations should be reserved only for the most extreme circumstances as complications following these procedures due to repeat obstructions and leakage with abdominal sepsis are not insignificant.

Another option is to place an endoscopic stent either for temporary decompression or for definitive palliation of unresectable lesions. Multiple studies over the past 10 years have demonstrated the feasibility and safety of this maneuver in selected patients.¹⁸⁹⁻¹⁹⁴ As a bridge to surgery, stenting can provide a minimally invasive means for converting an emergency situation into an elective one, allowing time for resuscitation, bowel prep, and adjuvant therapies. In a small randomized, controlled trial from 2009, Cheung et al.¹⁹⁵ reported additional advantages including significantly reduced rates of perioperative morbidity and stoma creation.

While short-term data seem to support the use of self-expanding metallic stents (SEMS) as a bridge to surgery, other reports as well long-term results from a recent comparative trial do not.^{196,197} Sabbagh et al.¹⁹⁸ performed a head-to-head, intention-to-treat analysis of 87 patients undergoing either stenting or emergency surgery, using a propensity score to correct for selection bias. Overall survival at 3 and 5 years was significantly better in the surgery group (66% versus 44%, $p = 0.015$, and 62% versus 25%, $p = 0.0003$, respectively) and remained superior even when patients with perforation and metastatic disease were excluded (74% versus 51%, $p = 0.02$, and 67% versus 30%, $p = 0.001$, respectively). Five-year cancer-specific mortality was significantly higher in the SEMS group (48% versus 21%, $p = 0.02$) and there were trends toward worse 5-year DFS and increased recurrence as well as mean time to recurrence. Based on these findings, the authors have markedly changed their management of left-sided malignant obstruction,

now reserving SEMS strictly for palliative indications and patients with high postoperative mortality risk.¹⁹⁸

Laparoscopic Colon Resection

Since its introduction to the field of general surgery for gallbladder resection, the use of laparoscopic surgery has found increasing applications.¹⁹⁹ Laparoscopic surgery has become a particularly important addition to the armamentarium of the surgical oncologist. The use of laparoscopy for the staging of the extent of disease for peritoneal malignancies, pancreatic cancer, colon cancer, and gastric cancer is now widely accepted.^{200–202} Laparoscopic resection has also found a niche for the removal of adrenal tumors, the spleen, and distal pancreas.^{203,204} The use of laparoscopic approaches for the resection of malignant lesions in the colon is now becoming more common.

With the increasing application of laparoscopic techniques to colon cancer surgery, concerns ranging from inadequacy of resection margins, inadequacy of LN sampling, and the potential seeding of port sites with malignant cells have been raised.^{205–207} Although these concerns are important, there are several potential advantages for laparoscopic approaches to the surgical management of colon cancer. Issues regarding length of incision, patient recovery time, and return to bowel function are often cited as justification for a laparoscopic approach. However, just as important are the technical advantages of surgery utilizing laparoscopic systems. The improved visualization due to magnification provided by video laparoscopy allows much more intricate and careful dissections in the deep pelvis, which could potentially reduce postoperative morbidity from low anterior resections that utilize a mesorectal excision technique. The ability to carefully trace vessels in the mesentery under magnification could improve the ability to perform high ligations in order to retrieve a greater number of LNs for sampling.

The technical difficulties faced during laparoscopic resection of the colon relate, in general, to the size of the specimen being removed and the need to perform an anastomosis. Each of these can be overcome through careful placement of incisions for specimen removal as well as a judicious use of stapling devices in order to perform both intracorporeal as well as a combination of intracorporeal and extracorporeal anastomotic techniques. A number of studies have examined the relative risks and benefits of the laparoscopic resection of colon cancer.^{205,208–210} A prospective random assignment trial conducted by Clinical Outcomes of Surgical Therapy Study Group examined both the oncologic outcomes with respect to DFS and overall survival as well as the impact of laparoscopic versus open surgery on patient recovery, pain management, and time to return of bowel function. An initial report on quality of life showed only a modest short-term benefit for laparoscopic resection versus a conventional open procedure,²¹¹ but the overall results of the trial with respect to oncologic outcomes demonstrated equivalence between the laparoscopic and open approach.²¹²

Long-term follow-up from the corresponding UK randomized study (CLASICC Trial Group), which was similarly designed to compare laparoscopic to conventional surgery for colon and rectal cancer, and that initially reported noninferiority results in 2007, lends further support to the laparoscopic approach. With a median follow-up of 62.9 (range, 22.9 to 92.8) months, the authors found no statistically significant differences in overall survival (82.7% versus 78.3%), DFS (77% versus 89.5%), or local recurrence.^{213,214}

Over a period of 10 years, the group from the Colon and Rectal Clinic of Orlando, Florida, performed a prospective nonrandomized study comparing laparoscopic to open resection for colorectal carcinoma. Laparoscopic resection was offered selectively in the absence of a large mass, invasion into the abdominal wall or adjacent organs, or if the patient did not have multiple prior operations.²⁰⁵ All laparoscopic resections were performed with curative intent, and 20% of the patients whose procedures were converted to open resection were included in the laparoscopic resection group based

on an intention-to-treat model. The study measured oncologic outcomes and compared them with a computerized case-matched open resection group, using case-matching variables consisting of age, gender, site of primary tumor (colon versus rectum), and TNM stage. The group who received laparoscopic resection was followed prospectively and the data were updated on a regular basis. Follow-up of these patients consisted of a combination of office visits, telephone calls, and a review of the US Social Security Death Index Database. There were 172 patients in each group, and the groups were well matched for age, TMM stage, prior chemo- or radiation therapy, and site of the primary tumor (colon versus rectum).

Thirty-day mortality was 1.2% in the laparoscopic resection group and 2.4% in the open resection group; however, this difference was not statistically significant. The local recurrence rate of the laparoscopic group was 3.5% compared to a local recurrence rate in the open group of 2.9%. The stage-for-stage overall 5-year survival rate between the two groups was similar, and the conclusion of the authors, while acknowledging drawbacks based on the nonrandomized nature of the study, was that there was no significant difference in outcomes between using laparoscopic approaches versus an open approach in the management of primary colon and rectal tumors. There was, however, no formal cost analysis in this study, and, therefore, although oncologic outcomes were no different between the two groups, it is impossible to determine whether one group was superior to the other with respect to other outcomes.

A case-matched comparison of clinical and financial outcomes following laparoscopic and open colectomy has been performed.²⁰⁶ The group at the Cleveland Clinic studied patients from a prospective database who had undergone laparoscopic or open colectomy and were matched for age, gender, and disease-related groupings. A group of 150 patients undergoing laparoscopic colectomy was compared to a matched group of patients undergoing open colectomy. There was no difference found between the two groups for diagnosis, complications, or 30-day readmission rate. Although operating room costs were significantly higher after laparoscopic colectomy, this was offset by a decrease in the length of hospital stay with an overall significant reduction in total costs. This is attributed mainly to a lower cost for pharmacy, laboratory, and ward nursing expenses.

The ultimate role of laparoscopic resection in the management of CRC has yet to be determined. The studies discussed have shed some light on the relative risks and benefits as well as costs of these two procedures. The questions will remain, however, if the procedures are equivalent and whether deviating from the accepted gold standard of open resection for the management of CRC will be warranted. Longer follow-up will hopefully assist in this assessment.

In the meantime, exploration of other minimally invasive approaches to resection is ongoing. Early studies report the feasibility and safety of single port surgery, or “SILC” (single-incision laparoscopic colectomy), as well as equivalent oncologic outcomes at 2 years, and robotic colectomy has also been performed although its greatest potential is thought to lie with rectal dissection.^{215–221} Natural orifice surgery is another area of interest with data accumulating on transvaginal specimen extraction as well as a pure transrectal approach.^{222–224} Whether any of these novel modalities will offer real advantages (other than cosmesis) to offset the significant drawbacks of increased technical difficulty, operating time, and cost remains to be seen.

POLYPS AND STAGE I COLON CANCER

The management of polyps and stage I colon cancer is through surgical resection. Most cancer in polyps is not diagnosed until after the polypectomy is performed. Therefore, with respect to pedunculated lesions, care should be taken to resect the stalk completely, down to its base. Invasive early stage I cancers found in a polyp managed by polypectomy do not require further resection if there

is a negative margin >2 mm and the tumor is well-differentiated without lymphovascular invasion or extension of malignant cells beyond the stalk (Haggitt levels 1 to 3).^{173,225} Sessile lesions that are biopsied and shown to harbor an invasive cancer should be managed with a segmental colon resection. Large polypoid lesions may also require a segmental resection.

Because the stage of the lesion will not be determined until after the resection, all colon cancer lesions managed with a segmental resection should be approached the same way. The type of resection will be dictated by the location of the lesion, as has been described. Following a complete resection of a stage I lesion, no further adjuvant therapy is required. Patients managed in this way can expect a 5-year survival of over 95%.²²⁵ Those that recur are most likely improperly classified stage II or III lesions.

STAGE II AND STAGE III COLON CANCER

Adjuvant Chemotherapy Considerations

The earliest clinical trials of adjuvant chemotherapy in colon cancer were conducted in the 1950s, utilizing the limited arsenal of anticancer agents that were available at that time. Many of these agents are now known to have no meaningful activity in metastatic CRC, and thus would not be studied in the adjuvant setting today.

The adjuvant trials of the 1950s through the mid-1980s tended to be small by current standards. Based perhaps on an unrealistically optimistic expectation of what magnitude of benefit might be achieved from the use of available chemotherapies, the size of the trials did not allow evaluation of more modest clinical benefits. A large meta-analysis of controlled randomized trials of adjuvant therapy published through 1986 indicated a nonsignificant trend toward an overall survival benefit, with a mortality OR of 0.83 in favor of therapy (95% CI = 0.70 to 0.98).²²⁶ This sobering analysis suggested that substantially larger trials would be needed to detect the modest advantages that available chemotherapies might afford.

Large-Scale Randomized Trials

The large-scale 5-FU trials have been well summarized previously, and the reader who is interested in the details is referred to subject-relevant chapters in the previous edition of this book.²²⁷ The outcome of numerous trials performed largely in the 1990s can be briefly summarized as follows. Trials comparing 5-FU-based therapy to surgery only demonstrated a clear benefit in terms of 5-year DFS (essentially, an increased cure rate) for stage III patients who received chemotherapy.^{228,229} Six months of chemotherapy was sufficient, and no further benefit was provided by extending treatment to either nine or twelve months. Levamisole, an agent initially thought to be active, was, in fact inactive, and high-dose leucovorin did not confer superior efficacy over low-dose leucovorin, so comparisons of various 5-FU/leucovorin schedules did not demonstrate clear superiority of one schedule over the other in terms of efficacy. However, the Mayo Clinic daily times five schedule was substantially more toxic than either weekly bolus or biweekly infusion schedules. Alfa interferon conferred substantial toxicity and provided no benefit.²³⁰⁻²³⁴

Oral Fluoropyrimidine Therapies

Oral administration of 5-FU proved to be problematic secondary to erratic bioavailability. This was likely due in large part to variable effects of DPD, the rate-limiting enzyme in catabolism of 5-FU, on the first pass clearance of oral 5-FU by the liver. Two oral 5-FU prodrugs, capecitabine and uracil/tegafur (UFT), have demonstrated efficacy in metastatic disease that is comparable to the Mayo Clinic schedule of parenteral 5-FU/leucovorin. Both of

these agents have now been studied in the adjuvant setting in comparison to the now defunct Mayo Clinic 5-FU schedule. In a study designed to assess for noninferiority in 3-year DFS, Twelves et al.²³⁵ randomly assigned 1,987 patients with resected stage III colon cancer to receive either oral capecitabine (1,004 patients) or Mayo Clinic bolus 5-FU plus leucovorin (983 patients). Each treatment was planned for 24 weeks. DFS in the capecitabine group was at least equivalent to that in the 5-FU/leucovorin group (in the intention-to-treat analysis [$p < 0.001$] for the comparison of the upper limit of the HR with the noninferiority margin of 1.20), and capecitabine resulted in significantly fewer adverse events than Mayo Clinic bolus 5-FU/leucovorin ($p < 0.001$). Overall, this trial demonstrates that capecitabine is a reasonable alternative to intravenous 5-FU/leucovorin in the adjuvant treatment of colon cancer in reliable, motivated patients who are able to comply with a complex schedule of oral medication. However, as discussed in the following, while possibly appropriate for some stage II patients, 5-FU/leucovorin alone is no longer the standard post-surgical adjuvant treatment for stage III colon cancer. As such, the role of single-agent capecitabine in the adjuvant management of resected colon cancer remains limited at this time. Data supporting its use with concurrent intravenous oxaliplatin are discussed subsequently.

The NSABP C-06 trial assessed the use of oral UFT plus oral leucovorin in the treatment of stage II and III colon cancer.²³⁶ A total of 1,608 patients with stage II (47%) and stage III (53%) colon cancer were randomly assigned to receive either oral UFT with leucovorin or intravenous 5-FU with leucovorin. With a median follow-up of 62.3 months, there were no significant differences in DFS or overall survival between the treatment groups. Toxicity and primary quality of life end points were similar in the two groups. As such, similar to the situation with capecitabine, the combination of oral UFT with leucovorin is an acceptable alternative to parenteral 5-FU/leucovorin; however, use of fluoropyrimidine plus leucovorin alone is no longer routine standard practice (see the following) in the adjuvant treatment of at least stage III disease. Furthermore, UFT is not commercially available in the United States.

Combination Adjuvant Therapies

Clinical trials in the metastatic setting have established the antitumor activity of combinations of agents, including irinotecan, oxaliplatin, bevacizumab, cetuximab, and panitumumab (see discussion of treatment of metastatic disease for more details). Although it had been assumed that activity in the metastatic setting would translate into an increased cure rate in the adjuvant setting, this assumption has turned out to be overly simplistic and often untrue. Of the agents listed previously, only the addition of oxaliplatin to fluoropyrimidines has resulted in benefit in the adjuvant setting.

Oxaliplatin

Oxaliplatin plus biweekly infusional 5-FU/leucovorin was first evaluated in the adjuvant setting in the Multicenter International Study of Oxaliplatin/5-Fluorouracil/Leucovorin in the Adjuvant Treatment of Colon Cancer (MOSAIC) trial.²³⁷ The results of this trial are summarized in Table 57.8. A total of 2,246 stage II and III patients were randomized to the LV5FU2 regimen, a biweekly infusional and bolus 5-FU/leucovorin regimen that has been demonstrated to have comparable efficacy to the Mayo Clinic daily times five bolus schedule in the adjuvant setting, or to the FOLFOX-4 regimen, which is LV5FU2 plus oxaliplatin on day 1.²³⁰ For the combined stage II and III study population, the 5-year DFS rates were 73.3% and 67.4% in the FOLFOX-4 and LV5FU2 groups, respectively (HR = 0.80; 95% CI = 0.68 to 0.93; $p = 0.003$).²³⁷ Six-year overall survival rates were statistically significantly improved by 2.5% (78.5% versus 76.0% in the FOLFOX-4

TABLE 57.8

Results of The Mosaic Trial: Biweekly Infusional Fluorouracil/Leucovorin Versus 5-Fluorouracil/Leucovorin Plus Oxaliplatin in Patients with Stage II and III Colon Cancer

	FOLFOX (%)	5FULV2 (%)	P Value
Five-y disease-free survival (stage II+III)	73.3	67.4	0.003
Six-y overall survival (stage II+III)	78.5	76.0	0.046
Six-y overall survival (stage III only)	72.9	68.7	0.023
Six-y overall survival (stage II only)	85	83.3	0.65
Grade 3–4 neutropenia	41	5	
Grade 3–4 diarrhea	11	7	
Grade 3 neuropathy	12	0	
Grade 2 neuropathy	32	0	

FOLFOX, fluorouracil/leucovorin plus oxaliplatin; 5FULV2, fluorouracil/leucovorin.

and LV5FU2 groups, respectively; HR = 0.84; 95% CI = 0.71 to 1.00; $p = 0.046$). For the stage III population, the 6-year overall survival rates were improved by 4.2% (72.9% versus 68.7%, respectively; HR = 0.80; 95% CI = 0.65 to 0.97; $p = 0.023$), whereas for the stage II population, the addition of oxaliplatin conferred no survival benefit (6-year survival 85.0% and 83.3%, respectively; $p = 0.65$). A more recent update showed that even amongst the stage II patients with high-risk factors, an improved outcome with the addition of oxaliplatin was not evident. While toxicity was regarded as manageable, the FOLFOX-4 regimen resulted in 41% grade 3 or 4 neutropenia versus 5% in the control arm, and 11% grade 3 or 4 diarrhea versus 7%. All-cause mortality in the first 60 days was 0.5% in each arm. Peripheral sensory neuropathy, a toxicity not present in the LV5FU2 control arm, was a frequent occurrence on the FOLFOX-4 arm. Grade 2 neuropathy was reported in 32% of the patients, and grade 3 occurred in 12%. In some cases, the duration of the neuropathy was substantial. One year after completion of therapy, 30% of patients still experienced some grade of neuropathy (0.8% grade 2 and 1.3% grade 3). Four years after completion of therapy, 15.4% still had some degree of neuropathy, and 0.7% still had grade 3 neuropathy. It is reasonable to assume that the toxicity still present at 4 years out from the last treatment is essentially permanent.

Oxaliplatin has also been combined with a weekly bolus 5-FU regimen in an adjuvant trial. The NSABP C-07 trial studied the FLOX regimen of oxaliplatin given on weeks 1, 3, and 5 plus weekly bolus 5-FU/leucovorin on weeks 1 through 6, repeated at 8-week cycles, versus the standard weekly Roswell Park regimen of 5-FU/leucovorin.²³⁸ A total of 2,409 patients were randomized to FLOX or to 5-FU/leucovorin. A total of 29% of patients had stage II disease and 71% had stage III. With a median follow-up of 8 years, FLOX showed a superior DFS, with 69.4% versus 64.2% alive and free of disease at five years (HR = 0.82; 95% CI = 0.72 to 0.93; $p = 0.002$). However, the overall survival difference was not statistically significantly different between the two arms. Treatment-related deaths were 1.3% versus 1.1% in the FLOX and 5-FU/leucovorin arms, respectively. Grade 2 or higher neurotoxicity was reported in 30.4% of patients on the FLOX arm versus 3.6% on 5-FU/leucovorin. Grade 3 diarrhea was 38.1% and 32.4% in the two arms, respectively, reflecting the higher incidence of serious diarrhea with the weekly bolus 5-FU regimen. Kidwell et al.²³⁹ published long-term data regarding the persistent neurotoxic side effects of oxaliplatin beyond 4 years from this same NSABP C-07 trial, and found that there was a statistically but not clinically significant increase in total neurotoxicity for those who received the agent, with initial differences between the two groups dissipating by 7 years. However specific symptoms of numbness and

tingling in the hands and feet did remain substantially elevated over time.²³⁹

Another recent study examined the effect of diabetes and other comorbidities on oxaliplatin-induced neuropathy. With symptoms identified in 65% of patients, hypertension, smoking, and diabetes were associated with higher trends although not statistically significant differences in severe neuropathy. Additionally, patients with diabetes developed oxaliplatin-induced neuropathy at a significantly lower cumulative dose, highlighting the importance of tailoring patient-specific regimens to minimize toxicity.²⁴⁰

In an exploratory analysis, however, the authors noted significant age-related differences in response to oxaliplatin, finding statistically improved overall survival in patients <70 years old, whereas older patients actually fared worse with increased grade 4-5 toxicity (OR = 1.59) and a 4.7% decrease in 5-year overall survival.

This age-treatment interaction has also been supported by a 2012 pooled analysis of 5,489 patients >75 years old from four large data sets that demonstrated minimal benefit of oxaliplatin in this group.²⁴¹ Moreover, post hoc analysis of MOSAIC data as well as revised findings from the ACCENT study (which initially showed no age-related difference) further indicate the limited clinical utility of this agent in older patients.^{241,242} Taking all this into account, the 2013 National Comprehensive Cancer Network (NCCN) guidelines now recommend individualizing the decision to add oxaliplatin to adjuvant regimens in the elderly.²⁴³

More recently, a 1,866-patient study comparing capecitabine plus oxaliplatin (Cape/Ox) with bolus 5-FU/leucovorin in the adjuvant treatment of stage III colon cancer has been reported.²⁴⁴ The Cape/Ox regimen had a statistically significant DFS advantage over 5-FU/leucovorin, with 66.1% of patients alive and disease-free at 5 years with Cape/Ox versus 59.8% with 5-FU/leucovorin. The difference between arms in overall survival at 5 years favored the Cape/Ox arm by 3.4%; however, this difference did not reach statistical significance at the time of this analysis ($p = 0.15$). The efficacy results of the FOLFOX and Cape/Ox studies appear more similar than different at this point in time and appear to justify interchangeability of these regimens in the adjuvant setting. Data for FLOX regimens appear to show higher rates of serious or life-threatening diarrhea, and the lack of a statistically significant survival benefit at 6 years is notable. The higher degree of severe and life-threatening diarrhea seen with FLOX would appear to be a potential reason for favoring FOLFOX or Cape/Ox over FLOX, although in the absence of a head-to-head comparison, the relative safety and efficacy when comparing one or these regimens to the other is impossible to know with certainty. The Cape/Ox regimen is a reasonable consideration only in highly reliable, motivated

patients who can be expected to comply with taking multiple pills of capecitabine orally (typically three to five pills, twice daily) for 2 weeks on, 1 week off, in the setting of concurrent emetogenic intravenous chemotherapy.

Irinotecan

Based on improved overall survival in the first- and second-line metastatic settings, it was widely assumed that irinotecan would be beneficial to patients in the adjuvant setting.²⁴⁵⁻²⁴⁷ This assumption has turned out to be incorrect, however, and the results of the adjuvant trials with this agent underscore the importance of both performing trials in the adjuvant setting and waiting for the results of those trials before adopting changes in practice.

The CALGB studied the weekly schedule of irinotecan plus bolus 5-FU and leucovorin (IFL). Early safety analysis of this trial identified an alarming elevation in early mortality for the experimental arm on this trial, with 18 deaths within the first 4 months of treatment on the IFL arm versus 6 deaths within the same time period on the control arm ($p = 0.008$).²⁴⁸ At a median follow-up of 2.1 years in each arm, futility boundaries for both DFS and overall survival had been crossed; thus, the final result of this trial is that the addition of irinotecan provided no benefit, while increasing toxicity, including lethal toxicity.²⁴⁹

Results of adding irinotecan to biweekly infusional 5-FU/leucovorin (LV5FU2 versus FOLFIRI) were also negative. In the ACCORD 02 trial, 400 patients with high-risk stage III disease (defined as four or more positive nodes or perforated or obstructed primary tumors) were randomly assigned to LV5FU2 versus FOLFIRI. In this high-risk population, there was no benefit seen in the FOLFIRI group, and in fact the study trended insignificantly in favor of the nonirinotecan-containing arm (3-year DFS 60% for LV5FU2 versus 51% for FOLFIRI).²⁵⁰

A second, larger trial of LV5FU2 versus FOLFIRI was conducted by the PETACC-3 investigators.²⁵¹ The prespecified primary efficacy analysis of this trial was based on 2,094 patients with stage III disease. At a median follow-up of 6.5 years, there was no statistically significant difference in the 5-year DFS (56.7% versus 54.3% for FOLFIRI versus LV5FU2, respectively; $p = 0.1$) or in 5-year overall survival (73.6% versus 71.3%, respectively; $p = 0.94$). FOLFIRI was associated with an increased incidence of grade 3 or 4 GI events and neutropenia.

Taken together, the results of these three trials to evaluate irinotecan in the adjuvant setting clearly establish that despite having substantial activity in the metastatic setting, irinotecan has no meaningful activity, and no role, in the adjuvant treatment of colon cancer. Of interest, an analysis from the CALGB trial suggested that patients with MSI-H showed a benefit from inclusion of irinotecan in their adjuvant treatment; however, a similar, substantially larger analysis from the PETACC-3 trial contradicted this and showed no benefit from adding irinotecan in patients with MSI-H.^{252,253}

Bevacizumab

As detailed subsequently, bevacizumab has demonstrated the ability to favorably augment standard chemotherapy for metastatic disease and has become a part of standard management in that arena. This led to evaluation of this agent in the adjuvant setting. In the NSABP C-08 trial, 2,672 patients, 25% with stage II and 75% with stage III colon cancer, were randomized to receive modified FOLFOX-6, either alone or with bevacizumab.²⁵⁴ A design imbalance that could have been problematic had this been a positive trial, the FOLFOX was given for 6 months in each arm, while the bevacizumab was given both with the FOLFOX and then for an additional 6 months, for a total of 1 year of bevacizumab. This was, however, a fully negative trial, so the issues regarding the design of the trial are moot. With a median follow-up of 5 years, the addition of bevacizumab to FOLFOX did not improve either the DFS or the overall survival. DFS was 77.9% versus 75.1% ($p = 0.35$) for the study overall, and DFS was 73.5% versus 71.7% ($p = 0.55$) for the

stage III patients. Five-year overall survival was 82.5% versus 80.7% ($p = 0.56$) for the entire study, and 78.7% versus 77.6% for the stage III patients. There was a separation between the curves at the 1-year mark; however, this began to diminish a few months later and was all but absent by year 3. This finding suggests that bevacizumab did delay progression of micrometastases in some patients, but only for as long as it was continued. Bevacizumab did not contribute to the eradication of micrometastases and thus did not improve the cure rate in the adjuvant setting. Although some might choose to interpret these data to suggest that if bevacizumab were continued indefinitely, an improved survival *might* be seen, the long-term consequences of lifelong suppression of vascular endothelial growth factor (VEGF), as well as the psychological, social, and economic considerations involved, render such an approach inappropriate, especially considering that only a very small percentage of patients so treated would actually have the potential to benefit, if there is a benefit. Another trial, termed the AVANT trial, also explored the use of bevacizumab in the adjuvant treatment of stage III colon cancer, and also found no benefit.²⁵⁵ This study randomized 3,451 patients, 2,876 of whom had stage III disease, to FOLFOX4, FOLFOX4 plus bevacizumab, or Cape/Ox plus bevacizumab. The bevacizumab-containing arms did not achieve a statistically significant improvement in DFS. After a minimum of 60 months follow-up, overall survival data suggested a possible detriment with the addition of bevacizumab, as the survival in the two bevacizumab-containing arms trended toward inferior to the FOLFOX-alone control arm; however, these differences did not reach statistical significance.

Thus, the available evidence suggests that bevacizumab is not beneficial in the treatment of colon cancer in the adjuvant setting, and might, in fact, be harmful. Until and unless data to the contrary emerge, bevacizumab should not be used in the adjuvant treatment of stage II and III colon cancer.

Cetuximab

As outlined in detail in the following, cetuximab has demonstrated clinical activity in metastatic CRC, prompting investigation of its usefulness in the adjuvant setting. Intergroup trial N0147 randomized patients with stage III colon cancer to modified FOLFOX-6 with or without cetuximab.²⁵⁶ Once investigators became aware that the study included only patients whose tumors lacked mutations in the KRAS gene (see the following), the study was modified to obtain KRAS genotyping on all patients and to only enroll those with wild-type KRAS. Despite this selection, this large, adequately powered, randomized phase 3 trial showed no benefit for the addition of cetuximab to FOLFOX in the adjuvant treatment of patients with KRAS-wild-type stage III colon cancer. DFS and overall survival curves trended insignificantly in favor of the FOLFOX-alone control arm, and the addition of cetuximab was overtly harmful in patients >70 years of age. Cetuximab should therefore not be used in the treatment of stage III colon cancer.

Panitumumab

Panitumumab, like cetuximab, is a monoclonal antibody that blocks ligand binding to the EGFR. Although no investigations have been reported to evaluate panitumumab in the adjuvant setting, results in the metastatic setting suggest that panitumumab and cetuximab are extremely similar in terms of target, mechanism of action, mechanisms of resistance, and clinical activity. It is therefore extremely unlikely that these agents would differ in the adjuvant setting, and statements regarding cetuximab in this setting may be reasonably applied to panitumumab.

TREATMENT OF STAGE II PATIENTS

The optimal management of patients with stage II colon cancer remains undefined. Although the role of adjuvant therapy in patients with stage II colon cancer has not been firmly established,

it is interesting to see what practice patterns have been emerging. Using the SEER-Medicare linked database, Schrag et al.²⁵⁷ identified 3,151 patients age 65 to 75 with resected stage II colon cancer and no adverse prognostic features. Using Medicare billing records, they identified those patients who did or did not receive chemotherapy within 3 months of operation. Their review identified that 27% of patients received chemotherapy during the 3-month postoperative period. Younger age, white race, unfavorable tumor grade, and low comorbidity were associated with a greater likelihood of receiving treatment. The 5-year survival was 75% for untreated patients and 78% for those patients who received therapy in this nonrandomized comparison. After adjusting for known between-group differences, the HR for survival associated with adjuvant treatment was 0.91 (95% CI = 0.77 to 1.09). Thus, despite the lack of proven benefit, a substantial percentage of Medicare beneficiaries have received adjuvant chemotherapy for stage II disease.

Because stage II patients as a group have a relatively favorable prognosis, benefits from treatment could only be expected if either a highly efficacious therapy were used or if extremely large trials were done to detect very subtle differences. The International Multicentre Pooled Analysis of B2 Colon Cancer Trials meta-analysis provides one of the largest samples of stage II patients.²⁵⁸ A total of 1,016 stage II patients were randomized between 5-FU/leucovorin and surgery alone. The surgery-only arm had a long-term overall survival rate of 81% versus 83% for those stage II patients who received adjuvant 5-FU/leucovorin. This absolute difference of 2% closely approached, but did not reach, statistical significance.

More recently, published studies have not generated any consensus on this topic. In a large retrospective, population-based analysis of 3,716 patients undergoing surgery for stage II disease with or without adjuvant chemotherapy, there was a statistically significant survival advantage for the adjuvant group (12 years versus 9.2 years). However, this is not a randomized trial, and patients receiving chemotherapy were more likely to be younger, with left-sided lesions and a higher LN yield, all of which are now known to be favorable prognostic factors. As such, it is difficult to draw conclusions from this study.²⁵⁹ Another study that evaluated data from 24,847 patients, 75% of whom had one or more prognostic features, found no survival benefit from an adjuvant regimen.²⁶⁰ Finally, Wu et al.²⁶¹ performed a systematic review of 12 randomized controlled trials including both colon and rectal cancers that suggested some improvement in 5-year overall survival and DFS for both tumor sites as well as a significant reduction in recurrence risk for stage II colon cancers. While the review has substantial flaws that limit interpretation of these results, it does indicate that larger, higher-quality trials are warranted.²⁶¹ One such study underway is the SACURA trial, a multicenter, randomized phase 3 study designed to evaluate the superiority of a 1-year adjuvant regimen compared to observation in stage II colon cancer. Investigators will seek to identify “high-risk factors of recurrence/death” as well as predictors of efficacy and toxicity in the adjuvant arm. End points include DFS, overall survival, and recurrence-free survival as well as the incidence and severity of adverse events. Results from this trial will hopefully facilitate a definitive therapeutic strategy for stage II colon cancers moving forward.²⁶²

Several prognostic indicators have been identified that correlate with a higher risk for subsequent failure in stage II patients. These include obstruction or perforation of the bowel wall as well as other less-established risk factors, such as elevated preoperative or postoperative CEA, poorly differentiated histology, and tumors not demonstrating high levels of MSI, or an 18q deletion in colorectal tumors, which may correlate with a poor prognosis.^{145,263–265} Additionally cited poor prognostic factors include macroscopically infiltrating-type tumors, high serum CA 19-9 levels, extensive venous invasion, male gender, age >50 years old, and <12 dissected LNs.²⁶⁶ It appears that stage II patients with one or more of these risk factors have a poorer prognosis, one closer to patients with stage III disease. Whether adjuvant chemotherapy can provide similar benefits in these patients as it does in stage III

patients remains a matter of conjecture, and in the absence of definitive data, definitive recommendations on this topic cannot be made at this time. In fully informed high-risk stage II patients, it is reasonable to consider adjuvant treatment. All reports from the MOSAIC trial have shown no benefit for the addition of oxaliplatin to 5-FU/leucovorin in terms of overall survival of stage II patients. Uniquivocally, stage II patients lacking high-risk factors have not been shown to benefit from oxaliplatin, and considering the short- and long-term toxicities of this agent, oxaliplatin should not be used in the management of good-risk stage II patients. A recent update of the outcomes for stage II patients on the MOSAIC trial demonstrates no benefit to use of oxaliplatin, even in patients on the trial with one or more high-risk factors.²⁴² Whereas patients with exceptionally poor risk stage II tumors may still seem reasonable for consideration of oxaliplatin-containing regimens, these negative data suggest that routine use of oxaliplatin in most patients with stage II colon cancer is unlikely to be appropriate.

Impact of Microsatellite Instability on Treatment in Stage II and III Colon Cancer

Ribic et al.²⁶⁷ investigated the usefulness of MSI status as a predictor of benefit from 5-FU–based adjuvant chemotherapy in 570 stage II and III patients from five randomized trials in which no treatment control arm was used. MSI-H was exhibited in 95 patients (16.7%), MSI-L in 60 patients (10.5%), and MSS in 415 patients (72.8%). In the 287 patients who did not receive adjuvant chemotherapy, those with tumors exhibiting MSI-H had superior 5-year survival compared to patients with MSI-L or MSS tumors (HR = 0.31; $p = 0.004$). In the population of patients who received adjuvant chemotherapy, there was no difference in survival between the patients with MSI-H and patients without MSI-H ($p = 0.8$). In the patients with MSI-L or MSS tumors, chemotherapy resulted in improved survival versus no chemotherapy (HR = 0.72; $p = 0.04$). However, 5-FU/leucovorin did not improve survival in the patients with MSI-H tumors (Table 57.9).

5-FU/leucovorin was associated with improved outcome in both stage II and III patients with MSS or MSI-L, with an HR of 0.67 (95% CI = 0.39 to 1.15) in stage II patients and 0.69 (95% CI = 0.47 to 1.01) in patients with stage III cancer. In contrast, in patients with MSI-H tumors, treatment did not improve survival,

TABLE 57.9

Microsatellite Instability Versus Outcome with 5-Fluorouracil-Based Adjuvant Chemotherapy

	No. of Patients	Five-Y Disease-Free Survival (%)	P Value
All Patients			
Adjuvant chemotherapy	285	70	0.06
No adjuvant chemotherapy	287	62	
Patients with MSI-L/MSS			
Adjuvant chemotherapy	230	70	0.01
No adjuvant chemotherapy	245	59	
Patients with MSI-H			
Adjuvant chemotherapy	53	69	0.11
No adjuvant chemotherapy	42	83	

MSI-L, low level of microsatellite instability; MSS, microsatellite stable; MSI-H, high level of microsatellite instability. From Ribic CM, Sargent DJ, Moore MJ, et al. Tumor microsatellite-instability status as a predictor of benefit from fluorouracil-based adjuvant chemotherapy for colon cancer. *N Engl J Med* 2003;349:247–257.

and in fact was associated with a trend toward worse outcome for both stage II (HR for death = 3.28; 95% CI = 0.86 to 12.48) and stage III cancers (HR = 1.42; 95% CI = 0.36 to 5.56). Of note, an analysis of MSI status from the NSABP failed to corroborate the results of the Ribic et al.²⁶⁷ study, and the authors concluded that in their trial there was no interaction between MSI status and treatment effect, and that their data do not support the use of MSI-H as a predictive marker for chemotherapy benefit.²⁶⁸ However, an updated expansion on the data from the Ribic et al.²⁶⁷ report appears to corroborate the original findings, leading the authors of that study to suggest that MSI determinations should be performed on all stage II patients, and that stage II patients with MSI-H should not be treated with fluoropyrimidines alone.²⁶⁹ The Eastern Cooperative Oncology Group I is leading a trial (ECOG 5202) in which patients with MSI-H and absence of LOH in chromosome 18q are being selected for observation, on the hypothesis that these patients will have a highly favorable prognosis with observation alone, whereas others are being assigned to FOLFOX chemotherapy and randomized to with or without bevacizumab. This trial has accrued and data are pending at the time of this writing.

An analysis of data indicate that patients with MSI-H stage III tumors, while having a more favorable prognosis than MSS tumors, do nevertheless achieve benefit from, and in the absence of contraindications, should receive, 5-FU-based adjuvant therapy.²⁷⁰ This recommendation is further supported when considering oxaliplatin-based chemotherapy in stage III disease. This would be reasonable to expect, as platinum-DNA adducts are not removed by the mismatch repair enzymes that are deficient in MSI tumors. A more recent analysis of MSI impact in stage III disease in the N0147 trial suggested a more complex and nuanced impact, with MSI-H tumors having a favorable prognostic impact when arising in the right side of the colon, but actually having a negative prognostic impact when occurring in the left colon.¹⁴⁷ The reasons for this difference remain unclear; however, the different embryologic origins of the left and right colon, and the resultant different venous drainages, may contribute to this.

The incidence of MSI has more recently been shown to vary with stage of disease presentation, with 22% of stage II patients, 12% of stage III, and only 3.5% of stage IV patients found to exhibit MSI, consistent with the data that MSI-H is a favorable prognostic factor. Data from the PETACC-3 trial suggest that it is a strong prognostic factor in stage II disease; however, it was less so in stage III.²⁷¹⁻²⁷³

Other Molecular Markers

As the majority of stage II, and even stage III, patients do not benefit from adjuvant therapy, it would be highly desirable to be able to identify those patients who are both at risk for recurrent disease (i.e., harbor micrometastases) and those whose micrometastases are sensitive to, and will be eradicated by, a particular chemotherapy. At present there are no such validated markers, with the possible exception of MSI, as discussed previously. KRAS mutations have no prognostic value in the adjuvant setting, and as there is no role for use of anti-EGFR agents in the adjuvant setting, the expense of genotyping patients with less than stage IV disease is difficult to justify.^{273,274} BRAF mutations appear to be prognostic of poorer overall survival in stage II disease that is not MSI-H; however, this appears to be regardless of therapy, and so again it provides no information to inform treatment decision making.²⁷⁵ At present, no molecular test has been validated as useful for making adjuvant treatment decisions, and none should be utilized outside of a clinical trial. More recently, a genetic profiling assay utilizing 21-gene signature analysis has become available.²⁷¹ This assay has been shown to provide risk stratification with stage II patients who are classified as having from 8% to 22% chance of recurrence. However, there was no interaction with treatment, meaning that the test is prognostic, identifying relatively lower or higher risk

individuals, but it provided no guidance on whom to treat. Thus, despite the interesting data outlined in the following, it would appear to be of little value in decision making at this time.

Despite this limitation, research efforts have been increasingly focused on developing and refining such gene signatures over the past few years, with three that stand out presently, promising to improve and possibly replace current risk stratification models.²⁷⁵ Unfortunately, none of these approaches are able to predict who will or will not benefit from adjuvant chemotherapy. While these prognostic scores may be of scientific interest, at present they are not recommended for routine clinical use in NCCN guidelines, as they appear to offer little if any guidance in terms of treatment decisions.

The Oncotype DX Recurrence Score, which is the only externally validated assay available for commercial use, is based on a 12-gene signature that separates 3-year recurrence risk into low, intermediate, and high (12%, 18%, 22%, respectively), independent of clinicopathologic features, and with enhanced accuracy. It has been shown to be highly prognostic in stage II and III patients receiving 5-FU/leucovorin, and enables better discrimination of absolute oxaliplatin benefit as a function of risk. A recent analysis of long-term costs and outcomes in “average-risk” stage II colon cancers (T3, MSS) concluded that this signature, when applied appropriately, could potentially reduce adjuvant chemotherapy use by 17% with increased quality-adjusted life expectancy of 0.035 years and cost-savings of \$2,971 per patient.²⁷⁶

Another interesting signature, ColoPrint (Agendia Inc. USA, Irvine, CA), is an 18-gene prognostic classifier developed on fresh-frozen tumor tissue to identify 5-year metastasis-free survival. Separating patients into two risk categories, this assay is particularly precise in identifying low-risk stage II cases that be managed without chemotherapy irrespective of MSI status. It also appears to better classify high-risk patients than clinicopathologic factors alone. While the signature has been validated twice in retrospective trials, it is not yet available for commercial use. A large prospective clinical validation study is under way (PARSC: Prospective Analysis of Risk Stratification by ColoPrint) that may better clarify the role of ColoPrint specifically in the management of stage II disease.²⁷⁷

Colorectal Cancer DSA (Almac Diagnostics, Craigavon, United Kingdom) is the most recently reported signature, based on 634 genes, developed to identify stage II patients at higher risk of recurrence (HR = 2.53) and cancer-related death (HR = 2.21) at 5 years. It has been shown to perform independently of known prognostic factors. While this assay is also not available for commercial use at the time of this writing, a prospective validation trial in stage II patients is being planned.²⁷⁸

The lack of clear direction on the matter of treatment of good-risk stage II patients is reflected in a current consensus statement, which, while not recommending therapy for all stage II patients, does recommend a medical oncology consultation for the purpose of discussing the pros and cons of chemotherapy for all stage II patients.²⁷⁹

TREATMENT OPTIONS FOR STAGE III PATIENTS

It is clear that in the absence of medical or psychiatric contraindications, patients with node-positive colon cancer should receive post-operative chemotherapy. At the very least, a 5-FU-based regimen would appear to be appropriate, and approximately 6 months of therapy would be supported by the majority of trials. The daily times five Mayo Clinic schedule or a variant has been shown to be more toxic than other 5-FU/leucovorin schedules; therefore, daily times five schedules should not be used. Oral capecitabine or oral UFT/leucovorin are acceptable alternatives if a fluoropyrimidine-only approach is selected. At this time, the data for incorporation of oxaliplatin into the routine adjuvant treatment of colon cancer appears compelling, and the FOLFOX schedule is now the most widely used adjuvant therapy. FLOX is an acceptable alternative; however, nonrandomized comparisons suggest that FLOX may carry a higher

risk of serious diarrhea than FOLFOX. Cape/Ox is also an acceptable alternative in appropriately motivated and reliable patients. Although the pivotal adjuvant study was done with FOLFOX-4, in practice this regimen is rarely used, and the modified FOLFOX-6 regimen, which has been the basis for all FOLFOX-based National Cancer Institute Intergroup adjuvant and metastatic trials, is routinely used due to its greater convenience. The risk of peripheral neuropathy and the possibility of long-term neuropathy must be considered in the selection of therapy. At the time of this writing, FOLFOX or Cape/Ox are the regimens of choice in treatment of all patients with stage III colon cancer in the absence of specific contraindications. The long-term morbidity of oxaliplatin treatment has become more appreciated; however, it is anticipated that risk stratification strategies may become available in the near future to identify those patients who are likely to benefit from oxaliplatin treatment.

Irinotecan-based regimens should not be used in the adjuvant setting, as randomized data have shown increased toxicity and no long-term benefit. Bevacizumab, cetuximab, and panitumumab should also not be used in the adjuvant setting, as they add toxicity and expense, and do not add benefit.

Timing of Treatment

Traditionally, adjuvant chemotherapy is commenced within 8 weeks of surgery. However, this time frame is somewhat arbitrary, based largely on what has been mandated in clinical trials. A 2010 meta-analysis pooled data from 13,158 patients with stage II or III disease and concluded that delaying treatment beyond this interval was associated with inferior survival (RR = 1.20).²⁸⁰ However, these data are retrospective, nonrandomized, and fail to adequately consider the collateral implications of whatever medical and surgical conditions might have contributed to the delay in start of therapy. As such, these findings should be regarded as hypothesis-generating only, and certainly not definitive. Another study that included only stage III cancers found no such clear correlation. Secondary analysis did demonstrate a trend toward poorer outcomes after 8 weeks, particularly in younger patients (<66 years) as well as significantly inferior survival for patients beginning chemotherapy after 9 and 10 weeks (HR of death = 1.68 and 1.67, respectively).²⁸¹

Investigational Adjuvant Approaches

Portal Vein Infusion

The NSABP C-02 trial randomized 1,158 patients with Dukes A, B, or C colon cancers to either a 7-day portal vein infusion of 5-FU (600 mg/m² per day) or to surgery alone.²⁸² A modest, albeit statistically significant, advantage in DFS (74% versus 64% at 4 years) was demonstrated for the group who received intraportal chemotherapy; however, no difference was seen in the incidence of hepatic recurrences.

Similar findings were reported from a 533 patient trial performed by the Swiss Group for Clinical Cancer Research.^{283,284} In this trial, intraportal chemotherapy included 10 mg/m² mitomycin C by 2-hour infusion followed by a 7-day infusion of 5-FU at a dose of 500 mg/m² per day. The 5-year DFS and overall survival were modestly improved in the intraportal treatment versus surgery-only groups (57% versus 48%, and 66% versus 55%, respectively).

Subsequently, a large meta-analysis of intraportal chemotherapy trials involving over 4,000 patients in 10 randomized studies revealed only a 4% improvement in 5-year overall survival for the patients who received portal infusion. At present, intraportal adjuvant chemotherapy has not been accepted as routine practice and remains limited to clinical investigations.

Intraperitoneal Chemotherapy

A small, single-arm study explored the feasibility of immediate postoperative intraperitoneal floxuridine and leucovorin plus

systemic 5-FU and levamisole.²⁸⁵ A randomized trial of 241 stage II and III patients compared intraperitoneal plus systemic 5-FU/leucovorin to systemic 5-FU/levamisole.²⁸⁶ With 4 years' median follow-up, no benefit was seen for the stage II patients. Among the 196 eligible patients with stage III disease, however, a 43% reduction in mortality was seen. This small trial is encouraging but would require further corroboration before being accepted into standard practice.

Hyperthermic intraperitoneal chemotherapy has been explored as a possible means of providing a benefit in patients at high risk for developing peritoneal metastases. Sammartino et al.²⁸⁷ explored this hypothesis in a small case control study of patients with T3/4 lesions and mucinous or signet ring cell histology who underwent either standard resection or extended surgery (including omentectomy, bilateral adnexectomy, hepatic round ligament resection, and appendectomy) followed by hyperthermic intraperitoneal chemotherapy. The experimental group experienced statistically significantly decreased rates of peritoneal recurrence (4% versus 22%) as well as improved DFS (36.8 months versus 21.9 months; $p < 0.01$). Large randomized trials would be necessary, however, before nonresearch use of this highly aggressive and potentially toxic treatment strategy could be considered.²⁸⁷

Vaccines

Vaccination strategies endeavor to stimulate the patient's immune system to recognize and eradicate the patient's tumor cells. An ideal immunologic target molecule would be a highly antigenic epitope that is always expressed on the tumor and never expressed on normal tissue. Such an ideal target has yet to be identified; however, a number of approaches have been explored.

CEA is a commonly expressed antigen in colorectal carcinomas. Unfortunately, CEA does not appear to be particularly immunogenic. Several approaches have been pursued in an attempt to increase immune recognition of CEA. Thus, a number of avenues of investigation are being pursued; however, at this time the use of vaccine therapy for treatment of resected colon cancer remains highly investigational.

One tumor-associated antigen that may be a more promising candidate is the MUC1 glycoprotein, which is abnormally expressed on neoplastic cells in a hypoglycosylated form that induces humoral and cellular response. A vaccine based on this antigen was found to be highly immunogenic in the premalignant setting, inducing long-term memory responses and no significant toxicity when administered to patients with advanced colonic adenomas. Subsequent studies will determine whether these results translate into meaningful clinical outcomes.²⁸⁸

Active Specific Immunotherapy

Irradiated cancer cells maintain their immunogenicity; however, they are unable to proliferate. Active specific immunotherapy is a maneuver in which patients are immunized with a preparation of their own irradiated tumor cells plus an immunostimulant such as bacillus Calmette-Guérin. This technique has been explored for some time now as a potential adjuvant immunotherapy for CRC. Overall, trials have failed to show a benefit for the use of active specific immunotherapy in the management of colon cancer, and its use should remain limited to investigational settings.

Preoperative Chemotherapy

Investigators are currently exploring the role of preoperative chemotherapy in the management of nonmetastatic disease. A pilot phase of the first randomized trial to address this topic (FOX-TROT) has recently been completed, demonstrating the feasibility and safety of this approach in locally advanced, operable colon cancer. The 150 patients who underwent meticulous radiologic staging were randomly assigned to receive 6 weeks of preoperative oxaliplatin/5-FU/I-folinic acid followed by surgery and 18 weeks of postoperative chemotherapy or upfront resection followed by

24 weeks of treatment. There were no significant differences in postoperative morbidity between the two groups. While a small proportion of the patients receiving preoperative therapy had apparent progression during the time between staging and surgery, there were no tumor-related complications during this interval. Overall, preoperative therapy resulted in significant downstaging, including reductions in apical node involvement and incomplete resections as well as two pathologic complete responses. Whether these results will translate into improved survival and potentially change the accepted pathway for management of nonmetastatic disease remains to be seen. A larger phase 3 trial now under way will hopefully shed light on this issue in the near future.²⁸⁹

FOLLOW-UP AFTER MANAGEMENT OF COLON CANCER WITH CURATIVE INTENT

Follow-up after definitive management has two primary goals. First, patients with a history of CRC are at higher risk than the general population for a second colon cancer primary.^{290,291} A colonoscopic screening may benefit in the early detection of a second primary malignancy or detection of a benign polyp, which can then be resected, potentially preventing the development of an invasive cancer.

Second, surveillance may increase the chance of identifying local regional or distant recurrence that is potentially curable by surgery. It should be noted that it is this detection of potentially curable recurrent or second primary disease that justifies routine postoperative surveillance. To date, there are no compelling data that indicate that early detection of unresectable asymptomatic metastatic disease is of benefit to the patient. In other words, if recurrent disease is unresectable and therefore incurable, there is no urgency to identify it; there is no compelling evidence that the early initiation of palliative chemotherapy is of benefit in the asymptomatic, incurable patient. Although the choice of follow-up routine and which studies to include in that follow-up have been the subject of much debate in the colon cancer literature,²⁹²⁻²⁹⁵ subsequent analyses have shown that most interventions that have been considered are not value-added and not appropriate for routine use. The American Society of Clinical Oncology (ASCO) has recently updated its guidelines for postsurgical follow-up.²⁹⁶ These recommendations are for physical examination and blood CEA monitoring every 3 to 6 months for the first 3 years, and every 6 months for years 4 and 5. CT scans of the chest and abdomen are recommended once a year for the first 3 years. Positron emission tomography (PET) scans are specifically not recommended for routine screening and surveillance. NCCN guidelines differ only slightly in that they recommend annual CT scanning for up to 5 years and include CT scans of the pelvis. Colonoscopy is recommended at 1 year after resection (or 3 to 6 months after resection if a complete colonoscopy was not performed prior to surgery) and then 3 years later, and then every 5 years. CT scans

and CEA monitoring should not be continued beyond 5 years. Of note, older studies advocating routine monitoring of complete blood count, liver function studies, lactate dehydrogenase, chest X-rays, and fecal occult blood monitoring have not been supported by subsequent data, and none of these are recommended for routine monitoring of patients at this time. The role of CEA measurement in patients following definitive management of CRC has been controversial.^{94,297,298} ASCO carefully reviewed its utility in an additional panel guided in 1996.²⁹⁹ Their recommendation for CEA monitoring then, which was confirmed in the surveillance guideline panel review, was postoperative serum CEA testing to be performed every 3 months in patients with stage II or III disease for up to 3 years after diagnosis. An elevated CEA level, if confirmed by retesting, warranted further evaluation for metastatic disease.

This further workup of an elevated CEA typically consists of a colonoscopy and a CT scan of the chest, abdomen, and pelvis. If these studies are negative, the clinician is faced with a dilemma. The question of what to do in the face of a rising serum CEA level in the absence of imageable disease by conventional imaging modalities is one that has been addressed in clinical trials.³⁰⁰⁻³⁰⁵ Strategies to image CEA expression might improve upon the detection capability of standard imaging studies. Several studies were performed using immunoscintigraphy with an antibody directed against CEA or Tag72, a CEA-like glycoprotein (CEA scan and OncoScint [Cytogen Corp, Lonza Biologics, Princeton, NJ] scan, respectively).³⁰⁶⁻³⁰⁸ The results of these studies using antibody-directed immunoscintigraphy were variable, and at this time, CEA scintigraphy is no longer considered in standard care. In an older study, in order to more directly address this clinical dilemma, a prospective study was performed comparing CEA immunoscintigraphy to PET using 18-fluorodeoxyglucose (FDG) and blind "second look" laparotomy.³⁰³

In this study patients with a rising CEA level without imageable disease by CT scan of the chest, abdomen, and pelvis as well as colonoscopy and abdominal ultrasound were enrolled along with patients with a single site of otherwise resectable disease. All patients had a CEA scan performed as well as a PET scan with FDG. All patients who failed to demonstrate evidence of disease outside of the abdominal cavity went on to have an exploratory laparotomy by a surgeon who had no knowledge of the CEA or the FDG scan results. A second surgeon participated in the remainder of the exploration after thoroughly reviewing all studies including the nuclear medicine scans. Twenty-eight patients were studied in this fashion, and the trial demonstrated that PET scan with FDG was far superior to CEA scans in detecting recurrence; roughly 30% of the patients on the study potentially benefited by having recurrent disease treated at the time of surgery (Fig. 57.4).

Based on these findings, it appears that serum CEA surveillance following definitive management of a primary CRC is a reasonable surveillance technique. If the CEA level is elevated on repeat testing, imaging studies should be performed consisting of CT scans and a thorough evaluation of the colon with colonoscopy

Figure 57.4 From left to right, the *first panel* depicts a contrast-enhanced computed tomography scan image of a patient with a rising carcinoembryonic antigen following a definitive resection of a right colon cancer. The *middle and far panels* show the same region imaged with fluorodeoxyglucose position emission tomography. (From Libutti SK, Alexander HR Jr, Choyke P, et al. A prospective study of 2-[18F] fluoro-2-deoxy-D-glucose/positron emission tomography scan, 99mTc-labeled arcitumomab [CEA-scan], and blind second-look laparotomy for detecting colon cancer recurrence in patients with increasing carcinoembryonic antigen levels. *Ann Surg Oncol* 2001;8:779.)

performed as well. If no recurrence or second primary is detected, watchful waiting and repeat of CT imaging at approximately 3-month intervals versus a PET scan with FDG can be considered. If disease is discovered, it should be managed as indicated. If no disease is detected, then continued surveillance is warranted with repeat CEA levels and CT or magnetic resonance imaging at intervals.^{303,309}

The role of physical examination has also been evaluated.³¹⁰ The ASCO panel noted that no formal examination of the contribution of physician's history and physical examination to help outcomes of CRC has been performed. However, data from the larger studies of surveillance showed that 80% of recurrences were found by CEA testing, whereas only 20% were found by routine history and physical examination done at the same time.³¹¹ This has been confirmed by other studies.^{312,313} Although no direct effects were shown on history or physical examination about the impact and detection or outcome in the surveillance period, a physician-patient encounter provides a vital link for other studies that may influence outcome. Therefore, while not in itself substantiated by the data in the literature, it is felt that routine postresection visits be performed every 3 to 6 months for the first 3 years following resection and every 6 months during years 4 and 5.

The role of liver function tests as a means for detecting colorectal recurrence has also been carefully evaluated. No studies that were reviewed by the ASCO panel demonstrated any benefit for the routine use of liver function test measurements in the post-surveillance period.^{310,314} In fact, studies suggest that other routine blood tests such as CEA detected recurrence far earlier than liver function test abnormalities.⁹⁴ Therefore, the 2005 ASCO consensus panel did not recommend the routine use of liver function test measurements in the postresection surveillance period.

Routine fecal occult blood testing, routine complete blood counts, and routine chest X-rays were all not thought to be of benefit in postoperative surveillance. Although the panel was not in uniform agreement with respect to chest X-ray, it was thought that all three of these modalities should be reserved for the evaluation of the patient with evidence of recurrence such as a rising CEA level or a positive endoscopy. Each of these modalities in and of itself was not found to be useful.

The panel recommended that annual CT of the chest and abdomen (with pelvis for rectal cancer) be performed for 3 years in those patients at higher risk for recurrence who could be candidates for curative-intent surgery of a recurrence. With respect to colonoscopy and flexible proctosigmoidoscopy, the panel, after reviewing the literature, recommended that all patients have a colonoscopy for the pre- or perioperative documentation of the cancer and to ascertain that the remainder of the colon is free from polyps. Further, the panel agreed that the data were sufficient to recommend colonoscopy at 3 years to detect new cancers and polyps and then every 5 years if normal. However, they did not recommend routine annual colonoscopy as follow-up following definitive management of patients with CRC. Further, the panel concluded that colonoscopy was superior to flexible proctosigmoidoscopy and therefore should be performed as previously discussed for patients following both colon and rectal cancer surgery. Other studies have also supported the routine use of colonoscopic examination following definitive management of CRC.^{315,316}

A meta-analysis and systematic review of randomized trials to address the impact of close postoperative surveillance on overall survival following definitive management of CRC was also performed by Renehan et al.³¹⁷ A total of five randomized trials that met their inclusion criteria were reviewed, representing 1,342 patients. For four of the studies, intensive follow-up consisted of blood work including serum CEA, colonoscopy, physical examination, abdominal ultrasound, and CT scans. In one study, no CEA measurements or CT scans were performed. Follow-up in the intensive arm was performed every 3 months for 2 years and then every 6 months thereafter up to 5 years, with yearly CT scans and endoscopy. All five studies had a control arm subjected to a less aggressive follow-up regimen, which varied from study to study

ranging from no specific follow-up to interval laboratory tests and plain X-rays or ultrasound. They found that there was an absolute reduction in mortality of 9% to 13% by employing an aggressive follow-up regimen, consisting of serum CEA measurements and CT scans. Two studies in particular showed the greatest impact on survival.

In summary, a rational postoperative surveillance program would include CEA measurements every 3 to 6 months and a yearly CT scan of the chest, abdomen, and pelvis (for rectal cancer) for the first 3 years. Colonoscopy can be performed every 3 to 5 years following the resection. At the time of CEA measurements, a physician encounter should be scheduled where a discussion of patient symptoms and a physical examination can be performed. If a rising serum CEA is detected on two consecutive measurements in the absence of imageable disease by CT scan, a PET scan with FDG can be considered. Lesions found on colonoscopy should be managed appropriately either with colonoscopic resection or surgical management. These surveillance guidelines should allow for the early detection of either resectable recurrence or second primary lesions and therefore the potential to impact patient outcome.

SURGICAL MANAGEMENT OF STAGE IV DISEASE

For a select group of patients with metastatic CRC, complete surgical resection of stage IV disease (discussed in detail in Chapter 60) may be an option and may provide a long-term survival advantage. This is especially true with respect to metastatic sites in the liver and lung. Resection of locoregional recurrence can also benefit the patient with respect to local control and overall outcome. Numerous regional approaches have also been explored for the treatment of stage IV colon cancer depending on the organ or body cavity involved. Organ-specific infusional therapy, isolated or continuous perfusion therapy, radiofrequency ablation or cryotherapy, surgical debulking, and radiation are all technical approaches that have been performed. Many of these regional strategies as well as surgical metastasectomy will be discussed in separate chapters and therefore will not be specifically addressed here.

MANAGEMENT OF UNRESECTABLE METASTATIC DISEASE

Unresectable metastatic CRC is generally not curable with current technology. Management centers around palliation and control of symptoms, control of tumor growth, and attempts to lengthen progression-free and overall survival. Given the palliative nature of such treatments, extreme care must be taken to adequately assess each individual's potential for both benefit and harm from chemotherapy. Care must also be taken with surgical interventions as well. Quality-of-life issues must be frankly and objectively discussed with patients and their caregivers so that informed decisions can be made and expectations can be contained within a realistic framework. The issue of whether patients presenting with unresectable stage IV disease should have their primary tumors resected has been the matter of some debate. Although such resections had been routinely performed in the past, more recent data suggest that such interventions are not required, and may in fact be counterproductive. Temple et al.³¹⁸ reviewed the linked SEER-Medicare databases and found that of 9,011 elderly patients presenting with synchronous stage IV disease, that 72% had undergone resection of the primary, and that the 30-day mortality for these resections was 10%. In a retrospective review, Poultides et al.³¹⁹ demonstrated that 93% of 233 patients never required surgical intervention on their primary tumors. More recently, the NSABP C-10 trial prospectively addressed this question, treating

90 patients with unresectable stage IV disease and intact, asymptomatic primary tumors with initial medical management with FOLFOX-6 plus bevacizumab. Twelve patients (14%) experienced major morbidity due to the intact primary tumor. This study met its prespecified end points for acceptability of initial nonoperative management, and the investigators concluded that good performance status patients with asymptomatic primaries can be spared initial noncurative resection of their primaries.³²⁰

Surgical intervention can be a very effective method of palliation and is often indicated in cases of impending obstruction, perforation, bleeding, or pain. However, it can also be associated with high postoperative morbidity and mortality. Stillwell et al.³²¹ identifies several adverse prognostic factors that can guide clinicians considering surgical palliation versus other less aggressive maneuvers. In a retrospective analysis of 379 patients who underwent palliative resection, elderly (≥ 70 years) patients with advanced local disease or extrahepatic metastases were at greatest risk for postoperative mortality. Other independently associated factors included emergency operation and medical complications. Advanced nodal disease (N2) and poor tumor differentiation were significant predictors of decreased long-term survival.³²¹

The chemotherapy options available and the developmental work that supports their utility are outlined subsequently. It is of paramount importance to keep in mind that virtually all of the clinical trials done in patients with metastatic disease were performed by design on patients who were in good overall general medical condition. Entry criteria for most trials require a favorable performance status and acceptable bone marrow, renal, and hepatic function, and they often specify evidence of reasonable nutritional intake.

It is not reasonable to extrapolate the results of these trials to patients who do not conform to these entry criteria. The likelihood of benefit in a poor performance status patient is substantially diminished, and the likelihood of a serious adverse event is greatly increased. Patients with hepatic or renal dysfunction may be particularly prone to additional toxicity if the drug is cleared or metabolized by these organs. Patients with marginal nutritional intake may have their nutritional deficiencies further exacerbated by drugs that produce nausea or anorexia, and patients with partial or complete bowel obstruction or other causes of prolonged GI transit time may have increased toxicity from those drugs that undergo an enterohepatic recirculation.

Thus, chemotherapy for patients with incurable metastatic disease should be approached with appropriate caution. Good performance status in well-motivated patients with good bone marrow reserve and good organ function portend a significant potential for substantial benefits from chemotherapy and should be strongly considered for aggressive therapy. Patients with poor performance status and significant comorbidities should be considered for either less aggressive therapies or for supportive care only.

Fluorouracil

Virtually the entire history of chemotherapy for CRC has revolved around the use of 5-FU. Developed by Heidelberger et al.³²² and patented in 1957, it is a source of frustration and humility for investigators working to move beyond it that over 50 years later this agent remains at the very core of most chemotherapeutic approaches to CRC.

5-FU must be metabolized before it can exert cytotoxic activity. The details of 5-FU metabolism are covered in a separate chapter. The history of investigations of 5-FU in CRC treatment has been well summarized in previous editions of this book.²²⁷ 5-FU remained the only drug available to treat CRC for almost four decades, during which time numerous agents were studied for their ability to “biomodulate” 5-FU. Of these, only leucovorin remains in use today, and it is debatable whether this reduced folate truly contributes to the efficacy of 5-FU. Most studies that evaluate the same dose of 5-FU with or without leucovorin find that both activity and toxicity are increased in the leucovorin arm, whereas studies that evaluate single-agent 5-FU versus an equitoxic schedule of a lower dose of 5-FU plus leucovorin find equivalent activity. Nevertheless, use of leucovorin persists in most standard regimens today. Data comparing bolus versus infusional schedules of 5-FU show a slight benefit for infusions. These infusional schedules achieved widespread acceptance in Europe sooner than in the United States. It was not until the advent of combination schedules of 5-FU plus other active agents that the benefits of infusional schedules, especially in terms of improved toxicity, asserted themselves in North American practice. A selection of commonly used 5-FU regimens is outlined in Table 57.10.^{323–325}

TABLE 57.10

Commonly Used 5-Fluorouracil Regimens^a

Name of Regimen	Author (Ref.)	Schedule (All Agents Administered Intravenously)
Roswell Park	Haller et al., 1998 ³²¹	LV 500 mg/m ² over 2 hr; 5-FU 500 mg/m ² by bolus 1 hr into LV infusion. Treatments given weekly for 6 consecutive wk, repeated every 8 wk.
Low-dose weekly LV	Jager et al., 1996 ³²³	LV 20 mg/m ² over 5–15 min, followed by bolus 5-FU 500 mg/m ² ; treatments given weekly for 6 consecutive wk, repeated every 8 wk.
Protracted venous infusion	Lokich et al., 1989 ³²⁴	5-FU 300 mg/m ² /d by continuous infusion.
AIO (weekly 24-hr infusion)	Kohne et al., 1998 ³²⁵	LV 500 mg/m ² over 2 hr, followed by 5-FU 2,600 mg/m ² over 24 hr, repeated weekly.
LV5FU2	de Gramont et al., 1997 ³⁴¹	LV 200 mg/m ² over 2 hr days 1 and 2, followed by bolus 5-FU 400 mg/m ² /day 1 and 2, followed by 5-FU 600 mg/m ² over 22 hr days 1 and 2; cycle repeated every 14 d.
Simplified LV5FU2	Adapted from Andre et al., 1999 ³³³	LV 400 mg/m ² over 2 hr, followed by bolus 5-FU 400 mg/m ² , followed by 5-FU 1,200 mg/m ² /d times 2 d (2,400 mg/m ² over 46–48 hr); cycles repeated every 14 d.

LV, leucovorin; 5-FU, 5-fluorouracil; AIO, Arbeitsgemeinschaft Internistische Onkologie (Oncology Working Group, Germany).

^a Doses listed are recommended starting doses for good performance status patients with normal renal, hepatic, and bone marrow function. Individual dose adjustments may be required.

Capecitabine

Capecitabine is a 5-FU precursor that is administered orally. It is absorbed intact through the gut and then activated by a series of enzymatic alterations. Some data suggest that thymidine phosphorylase levels are higher in tumor than in normal tissue. This could, in theory, provide a degree of preferential intratumoral activation; however, clinical trials do not appear to support a substantially better therapeutic index than 5-FU.³²⁶ Phase 2 studies demonstrate that this agent has substantial activity in CRC, with an acceptable toxicity profile.³²⁷ Because the addition of leucovorin did not appear to show any benefit, clinical development went forward without additional biomodulation. Phase 3 randomized clinical trials, performed both in the United States and Europe, have now shown that this orally administered agent is at least as effective as intravenous 5-FU/leucovorin, and the side effect profile of capecitabine is superior to the daily times five Mayo Clinic schedule of 5-FU/leucovorin.^{328,329} However, as this bolus daily times five schedule is now known to be unacceptably toxic and is not used anymore, the relevance of the toxicity comparison is questionable. Head-to-head studies of modern infusional 5-FU/leucovorin regimens versus capecitabine have never been done; however, a reasonable extrapolation from available data would suggest that these two approaches are extremely similar in efficacy and tolerability. The dose used in these pivotal trials was 1,250 mg/m² given twice daily for 14 days followed by a 7-day rest. The major side effects of capecitabine appear to be palmar-plantar erythrodysesthesia, commonly called hand-foot syndrome, and to a lesser extent diarrhea. The hand-foot toxicity is frequently a dose-limiting side effect, and although the approved starting dose is 1,250 mg/m² twice daily, this dose is based on trials conducted mainly in Europe. For unclear reasons, possibly related to higher serum folate levels, American patients tolerate capecitabine less well than European patients, and clinicians in the United States often choose to initiate therapy at a lower dose and escalate if little or no toxicity is seen.

Irinotecan

Irinotecan (CPT-11) is a semisynthetic derivative of camptothecin, a plant alkaloid extracted from the wood of the Asian tree *Camptotheca acuminata*.³³⁰ CPT-11 possesses a bulky dipiperidino side chain linked to the camptothecin molecule via a carboxyl-ester bond. This side chain provides solubility but greatly decreases anticancer activity. Carboxylesterase, a ubiquitous enzyme with primary activity in the liver and gut, cleaves the carboxyl-ester bond to form the more active metabolite 7-ethyl-10-hydroxycamptothecin (SN-38).³³¹ SN-38 is as much as 1,000-fold more potent in

inhibiting topoisomerase I than irinotecan and is thus the predominant active form of the drug. CPT-11 is often considered to be a prodrug for SN-38; however, this concept may be a bit too simplistic, as achieved CPT-11 concentrations may be several logs higher than those of SN-38.

Camptothecin, CPT-11, and SN-38 function as inhibitors of topoisomerase I (topo I). Topo I is a nuclear enzyme that aids in DNA uncoiling for replication and transcription. When topo I binds to DNA, it causes a reversible single-stranded break in the DNA, allowing the intact strand to pass through the break to relieve torsional stress on the coiled helix, and then reseals the break. CPT-11 and SN-38 stabilize these single-stranded breaks. Although the stabilized breaks do not cause irreversible damage, the collision of replication forks with open single-stranded breaks results in double-stranded breaks, leading to lethal DNA fragmentation. The early development of irinotecan and its single-agent schedules have been well documented in earlier editions of this textbook.²²⁷

CPT-11 in First-Line Combination Regimens

Numerous phase 1 combinations of 5-FU, usually with leucovorin, plus CPT-11, were tried. Saltz et al.³³² reported a phase 1 trial built on the weekly CPT-11 schedule that had been selected for phase 1 development in North America. A low dose of weekly leucovorin was utilized in order to reduce the potential for 5-FU/leucovorin-induced diarrhea. The phase 1 trial showed that the full single-agent dose of 125 mg/m² of CPT-11 could be given with 500 mg/m² of 5-FU and 20 mg/m² leucovorin, with all drugs given weekly for 4 consecutive weeks followed by a 2-week break. This and other CPT-11/5-FU/leucovorin regimens are summarized in Table 57.11. This combination of IFL was compared to the Mayo Clinic schedule of 5-FU/leucovorin in a multicenter, multinational phase 3 trial.²⁴⁷ For regulatory reasons, a single-agent CPT-11 arm was included as well. The IFL arm was found to be superior to Mayo Clinic 5-FU/leucovorin in terms of response rate, time to tumor progression, and overall survival. The CPT-11-alone arm appeared to be comparable in efficacy to the 5-FU/leucovorin arm. The overall incidence of severe toxicity was similar in all arms of this trial. More serious diarrhea and vomiting were seen with IFL, while more neutropenia, neutropenic fever, and stomatitis were seen with 5-FU/leucovorin. Treatment-related deaths occurred in 1% of patients in each arm of this trial. Although this IFL schedule represented a step forward over the Mayo Clinic 5-FU/leucovorin schedule, neither of these are recommended for current use. As outlined in the following, the infusional 5-FU schedules have a superior safety and efficacy profile and are preferred for use, especially in combination regimens.

TABLE 57.11

Commonly Used Irinotecan/5-Fluorouracil Combination Regimens^a

Name of Regimen	Author (Ref.)	Schedule (All Agents Administered Intravenously)
FOLFIRI	Douillard et al., 2000 ²⁴⁶	Irinotecan 180 mg/m ² over 2 hr; LV 200 mg/m ² concurrently with irinotecan (can be given in same line through "Y" connector); followed by 5-FU bolus 400 mg/m ² , followed by 5-FU 600 mg/m ² infusion over 22 hr. Irinotecan given day 1 only. All other meds given days 1 and 2. Cycle repeated every 14 d.
FOLFIRI (simplified)	Andre et al., 1999 ³³³	Irinotecan 180 mg/m ² over 90 min; LV 400 mg/m ² concurrently with irinotecan (can be given in same line through "Y" connector); followed by 5-FU bolus 400 mg/m ² , followed by 5-FU 1,200 mg/m ² /d times 2 d (2,400 mg/m ² infusion over 46–48 hr). Cycle repeated every 14 d.
FUFIRI	Douillard et al., 2000 ²⁴⁶	Irinotecan 80 mg/m ² , then LV 500 mg/m ² , followed by 5-FU 2,300 mg/m ² ; all drugs given weekly for 6 wk, repeated every 7 wk.

FOLFIRI, irinotecan, 5-FU, LV; LV, leucovorin; 5-FU, 5-fluorouracil; FUFIRI, 5-FU, LV.

^a Doses listed are recommended starting doses for good performance status patients with normal renal, hepatic, and bone marrow function. Individual dose adjustments may be required.

In Europe, a parallel study to investigate the benefit of adding irinotecan to a 5-FU–based schedule was undertaken.²⁴⁶ Two high-dose intermittent infusional schedules were developed. In France, a biweekly treatment for 2 consecutive days was explored, while German investigators, building on their experience with weekly 24-hour high-dose infusions of 5-FU, combined CPT-11 with this schedule. A randomized phase 3 trial was performed in which a participating center chose which of these two schedules would be used, and then the patients were randomized to that 5-FU/leucovorin schedule plus or minus CPT-11. Again, response rate, progression-free survival, and overall survival were superior in the CPT-11–containing arm of the trial. Of note, only the cohort treated with the biweekly schedule demonstrated a statistically superior survival over the 5-FU/leucovorin control arm, and the biweekly combination schedule is the only one registered for use in the United States.

More recently, the biweekly schedule of LV5FU2 plus irinotecan has been studied with a simplified LV5FU2 infusion schedule.³³³ This schedule, known as FOLFIRI (FOL for folinic acid, F for 5-FU, and IRI for irinotecan), was initially studied as a salvage regimen; however, this has now gained widespread acceptance as a first-line treatment option, based on the data discussed subsequently.

The BICC-C (Bolus, Infusional, or Capecitabine with Campsar-Celecoxib) trial is the only trial to directly compare weekly bolus IFL to FOLFIRI.³³⁴ This trial utilized a modified bolus IFL schedule, giving treatment on days 1 and 8, repeated on a 3-week cycle. This modified IFL was compared to FOLFIRI as well as to capecitabine/irinotecan. The first phase of this trial (430 patients) confirmed the superior safety and efficacy of FOLFIRI over IFL (median progression-free survival 7.6 months for FOLFIRI versus 5.8 months; $p = 0.007$) and over capecitabine/irinotecan (progression-free survival 5.7 months; $p = 0.003$). The trial was halted when bevacizumab (see the following) became commercially available, and a second phase randomized 117 patients to modified IFL plus bevacizumab versus FOLFIRI plus bevacizumab (capecitabine/irinotecan was dropped from the second phase of this trial). This second phase showed a significant overall survival advantage for FOLFIRI/bevacizumab over modified IFL/bevacizumab ($p = 0.002$). The BICC-C trial also had a second randomization of all patients to celecoxib versus placebo. Celecoxib was found to provide no benefit in terms of either safety or efficacy and does not appear to have a role as part of standard chemotherapy of this disease.

Oxaliplatin

Oxaliplatin (1,2-diaminocyclohexane (trans-1) oxalatoplatinum) is a third-generation platinum compound of the diaminocyclohexane family. Initial single-agent phase 1 studies established that oxaliplatin could be safely administered, with evidence of clinical activity.^{335,336} No significant nephrotoxicity was seen. Nausea and vomiting, minimal leucopenia, and rare thrombocytopenia were observed. Extra et al.³³⁵ were the first to describe in detail the most notable toxicity encountered with oxaliplatin: neurotoxicity. This neurotoxicity manifested as paresthesias and dysesthesias of the hands, feet, perioral region, and throat. Pharyngolaryngeal dysesthesia, a sensation of choking without overt airway blockage, was described as well. These neurologic toxicities were induced or worsened by exposure to cold. Early single-agent explorations with oxaliplatin have been well outlined in the prior edition of this textbook.³³⁷

Oxaliplatin/5-Fluorouracil/Leucovorin Combination Trials

Based on a series of phase 2 trials by Levi et al., Giachetti et al.³³⁸ from the same group reported a phase 3 trial of chronomodulated

5-FU/leucovorin alone or with oxaliplatin.^{338–340} Two hundred patients were randomly assigned to receive a 5-day course every 3 weeks of chronomodulated 5-FU and leucovorin (700 and 300 mg/m² per day, respectively; peak delivery rate at 4 a.m.) with or without oxaliplatin on the first day of each course (125 mg/m², as a 6-hour infusion). The group who received oxaliplatin had a superior response rate (53% versus 16%; $p < 0.001$). Progression-free survival was also superior, just reaching statistical significance (8.7 months versus 7.4 months; $p = 0.048$). There were no differences in median overall survival (19.4 months and 19.9 months, respectively). Survival outcomes in this trial are somewhat difficult to interpret as extensive use of resection of metastatic disease was applied in both arms.

Most of the combination 5-FU/leucovorin/oxaliplatin trials have used flat (nonchronomodulated) administration of agents and have centered on variants of the FOLFOX regimen. The acronym FOLFOX (FOL for folinic acid [leucovorin], F for fluorouracil, OX for oxaliplatin) refers to a series of combinations of these agents. These are biweekly (every other week) regimens using 2 days of infusional 5-FU on a 14-day cycle (LV5FU2).³⁴¹ The FOLFOX-1, -2, and -3 regimens employed various alterations in dosing of each oxaliplatin, 5-FU, and leucovorin.^{342,343} They are of historical interest, but were never evaluated in randomized trials. FOLFOX-3 and FOLFOX-4 were reported in a combined series to have a response rate of 21% in a population of patients who had progressed on the same 5-FU/leucovorin schedule without oxaliplatin.³⁴² The FOLFOX-4 regimen had a modestly higher response rate and lower toxicity than FOLFOX-3 (which used higher doses of 5-FU and leucovorin), and FOLFOX-4 appeared to be better tolerated. The more commonly used oxaliplatin/5-FU/leucovorin combinations are outlined in Table 57.12.^{344,345}

A randomized phase 3 trial was undertaken to evaluate FOLFOX-4 versus the LV5FU2 schedule in patients with previously untreated metastatic CRC (essentially a trial of LV5FU2 with or without oxaliplatin).³⁴⁶ Patients treated with FOLFOX-4 had a statistically significantly superior outcome in terms of response rate (51% versus 22%; $p = 0.001$) and progression-free survival (9 months versus 6.2 months; $p = 0.0003$). The FOLFOX arm had a 1.5-month improvement in median overall survival; however, this did not reach statistical significance (16.2 months versus 14.7 months; $p = 0.12$). The number of patients experiencing grade 3 or 4 neutropenia was increased with FOLFOX-4 over 340 (42% versus 5% of patients). Grade 3 or 4 diarrhea (12% versus 5%) was also increased in the FOLFOX arm. Neurotoxicity, virtually absent in the LV5FU2 arm, was frequent in the FOLFOX arm, with 18% of patients experiencing grade 3 neurosensory toxicity.

The FOLFOX-4 regimen has also been evaluated in a multicenter randomized trial in second-line therapy following failure of first-line IFL chemotherapy.³⁴⁷ Patients were randomly assigned to one of three arms: FOLFOX-4, LV5FU2, or single-agent oxaliplatin. Response rates were 10% for FOLFOX, 0% for LV5FU2, and 1% for oxaliplatin alone ($p < 0.0001$ for FOLFOX versus LV5FU2). Time to tumor progression was also superior for FOLFOX-4 (4.6 months) versus LV5FU2 (2.7 months) and oxaliplatin alone (1.6 months). These data confirm initial clinical impressions that oxaliplatin/5-FU combinations have superior activity to single-agent oxaliplatin, even in 5-FU–refractory disease. FOLFOX-4 has activity in IFL-refractory disease; however, single-agent oxaliplatin essentially does not.

Further modifications have been made to the FOLFOX schedule. FOLFOX-5 was designed with an increased dose of oxaliplatin to 100 mg/m² every 14 days; however, this regimen was never tested in clinical trials. FOLFOX-6 utilized this 100 mg/m² oxaliplatin dose with a simplified 5-FU/leucovorin schedule.³⁴⁸ Oxaliplatin 100 mg/m² is given over 2 hours, with leucovorin 400 mg/m² given concurrently via a “T” connector. These are then followed by a 400 mg/m² bolus of 5-FU, and then a 46-hour infusion of 5-FU at 2,400 to 3,000 mg/m². More recently, the FOLFOX-7 regimen has been reported, utilizing a 130 mg/m² dose of oxaliplatin

TABLE 57.12

Selected Commonly Used Oxaliplatin/5-Fluorouracil Combination Regimens^a

Name of Regimen	Author (Ref.)	Schedule (All Agents Administered Intravenously)
FOLFOX-4	de Gramont et al., 2000 ³⁴⁶	Oxaliplatin 85 mg/m ² over 2 hr; LV 200 mg/m ² concurrently with oxaliplatin (can be given in same line through “Y” connector); followed by 5-FU bolus 400 mg/m ² , followed by 5-FU 600 mg/m ² infusion over 22 hr. Oxaliplatin given day 1 only. All other meds given days 1 and 2. Cycle repeated every 14 d.
FOLFOX-6	Tournigand et al., 2004 ³⁴⁹	Oxaliplatin 100 mg/m ² over 2 hr; LV 400 mg/m ² concurrently with oxaliplatin (can be given in same line through “Y” connector); followed by 5-FU bolus 400 mg/m ² , followed by 5-FU 1,200 mg/m ² /d times 2 d (2,400 mg/m ² infusion over 46–48 hr). Cycle repeated every 14 d.
Modified FOLFOX-6	Widely used in current phase 3 trials, Wolmark et al. 2009 ³⁴⁴	Oxaliplatin 85 mg/m ² over 2 hr; LV 400 mg/m ² concurrently with oxaliplatin (can be given in same line through “Y” connector); followed by 5-FU bolus 400 mg/m ² , followed by 5-FU 1,200 mg/m ² /d times 2 d (2,400 mg/m ² infusion over 46–48 hr). Cycle repeated every 14 d.
FUFOX	Grothey et al., 2002 ³⁴⁵	Oxaliplatin 50 mg/m ² over 2 hr, followed by LV 500 mg/m ² , followed by 5-FU 2,000 mg/m ² over 24 hr, weekly for 5 wk, repeated every 6 wk.

FOLFOX, folinic acid, 5-FU, oxaliplatin; LV, leucovorin; 5-FU, 5-fluorouracil; FUFOX, 5-FU, folinic acid.

^a Doses listed are recommended starting doses for good performance status patients with normal renal, hepatic, and bone marrow function. Individual dose adjustments may be required.

every 14 days. The simplified leucovorin/5-FU administration of FOLFOX-6 is maintained, with deletion of the bolus 5-FU. Oxaliplatin is discontinued after 3 months, with planned reintroduction after 12 weeks or sooner if clinical progression occurs.³⁴⁹ This rationale appears promising, both for treatment of metastatic disease and for potential use in the adjuvant setting. Given the similar response rates after 12 weeks, it would appear that the increased dose of oxaliplatin in FOLFOX-7 is unnecessary. A reasonable approach to standard use of FOLFOX in the metastatic setting is to use a modified FOLFOX-6, with 85 mg/m² of oxaliplatin and simplified LV5FU2 at a dose of 2,400 mg/m² over 46 to 48 hours (1,200 mg/m² per day for 2 consecutive days). As discussed in the following, the OPTIMOX trial data support cessation of oxaliplatin after 12 weeks and reintroduction of the oxaliplatin at a later date upon disease progression. It had been previously hypothesized that administration of high doses of calcium and magnesium with

oxaliplatin would be protective against neurotoxicity, but a definitive trial has now demonstrated that this is not the case.³⁵⁰

Comparisons of Oxaliplatin- and Irinotecan-Based Combinations

With both oxaliplatin- and irinotecan-based regimens showing encouraging activity, the question of which agent to use first was addressed by a number of investigators. Tournigand et al.³⁴⁹ reported a phase 3 trial of FOLFOX-6 versus FOLFIRI. This trial utilized identical simplified LV5FU2 schedules, with the only variable being oxaliplatin or irinotecan. All patients were planned to crossover to the other regimen at time of progression, and the primary end point was time to tumor progression after *both* chemotherapy regimens. Results are shown in Table 57.13. Although the study is somewhat underpowered at a total of 226 patients, the

TABLE 57.13

Comparison of First-Line Use of Irinotecan Versus Oxaliplatin in Conjunction with the Same Simplified Biweekly Infusional 5-Fluorouracil/Leucovorin Schedule

	FOLFIRI (n = 109 Patients Treated)	FOLFOX-6 (n = 111 Patients Treated)	P Value
Major objective response rate (partial plus complete responses)	56%	54%	0.68
Time to tumor progression (on first-line regimen)	8.5 mo	8.1 mo	0.65
Time to tumor progression (after first- and second-line regimen)	14.4 mo	11.5 mo	0.65
Overall survival (from initial randomization)	20.4 mo	21.5 mo	0.9
Two-yr overall survival	41%	45%	
Grade 3–4 neutropenia	25%	44%	
Neutropenic fever	6%	1%	
Grade 3–4 diarrhea	14%	11%	
Neuropathy (grade 3)	0%	34%	
Alopecia (grade 2)	24%	9%	

FOLFIRI, irinotecan, 5-fluorouracil, leucovorin; FOLFOX, folinic acid, 5-fluorouracil, oxaliplatin.

From Tournigand C, Andre T, Achille E, et al. FOLFIRI followed by FOLFOX6 or the reverse sequence in advanced colorectal cancer: a randomized GERCOR study. *J Clin Oncol* 2004;22:229–237.

results show a striking consistency between regimens, suggesting that use of either FOLFOX-6 or FOLFIRI in first-line treatment is acceptable. A somewhat larger trial of 360 patients randomized to FOLFOX-4 versus the equivalent FOLFIRI schedule, utilizing the same LV5FU2 dose and schedule in each arm, again shows comparable efficacy data, with differing and predictable toxicity profiles.³⁵¹

The North Central Cancer Treatment Group–led US Intergroup study N9741, a complex and important trial that underwent many iterations before its completion, initially opened as a four-arm trial comparing the Mayo Clinic 5-FU/leucovorin control arm to three different CPT-11/5-FU/leucovorin regimens: weekly bolus IFL as reported by Saltz et al.,²⁴⁷ a “Mayo II” schedule of CPT-11 on day 1 and bolus 5-FU/low-dose leucovorin on days 2 to 5, or the biweekly infusional schedule of LV5FU2 plus CPT-11 as reported by Douillard et al.²⁴⁶ and Goldberg.³⁵² After accruing a small number of patients, the trial was closed to incorporate three oxaliplatin-containing arms: FOLFOX-4, IROX (a once every 3 weeks combination of irinotecan and oxaliplatin, without 5-FU), and a modified Mayo Clinic schedule of bolus 5-FU plus low-dose leucovorin days 1 through 5, with oxaliplatin given on day 1. The infusional LV5FU2 plus CPT-11 arm was dropped. This created a six-arm trial. In March 2000, the trial was again halted, based on presentation of evidence that the combination of CPT-11/5-FU/leucovorin, using either bolus or infusional schedules, was superior to 5-FU/leucovorin. The Mayo Clinic control arm of N9741 was now dropped, and weekly bolus IFL became the control arm. At the same time, ongoing real-time monitoring of fatal toxicities identified unacceptably high rates of treatment-related mortality in the oxaliplatin plus Mayo Clinic 5-FU/leucovorin and in the CPT-11 plus 5-FU/leucovorin arms. These schedules were also dropped from the trial and from further development, leaving a three-arm trial of CPT-11 plus bolus 5-FU/leucovorin (IFL), oxaliplatin plus infusional LV5FU2 (FOLFOX-4), and oxaliplatin plus CPT-11 (IROX).

The trial was stopped a third time in April 2001, when monitoring of the trial indicated what appeared to be a higher than expected early mortality in the IFL control arm.²⁴⁸ This observation, however, was based on utilization of a new metric, the 60-day ACM. This metric records death from *any* cause within 60 days of initial therapy. The 60-day ACM of the IFL arm was initially noted

to be 4.5%. Because this was a new metric, however, there were no readily available historical controls; no one had ready access to data to say what the 60-day ACM had been in previous trials, either with IFL or with 5-FU/leucovorin regimens. The 4.5% ACM was therefore compared to the previously reported death rate for the IFL regimen, which was 0.9%. However, the previously reported death rate was the treatment-related death rate, the percentage of deaths judged by the investigators to have been caused by treatment, not all deaths within 60 days of starting therapy. Of further concern to the safety monitoring committee, however, the experimental arms (FOLFOX-4 and IROX) each showed 60-day ACMs of 1.8% (compared to 4.5% for the IFL control arm). This information was difficult to put into context, however, because the efficacy of the two experimental arms had not yet been established.

In fact, the 60-day ACM on the original phase 3 trial of IFL (subsequently calculated after N9741 was halted) was 6.7%, and the 60-day ACM for the Mayo Clinic control arm of that trial was found to be 7.3%. Although the 7.3% 60-day ACM appeared subjectively to be unusually high, no historical baseline data on 60-day ACM in 5-FU–based regimens were readily available. To help interpret these data, an analysis was undertaken to determine the 60-day ACM in multiple large-scale randomized trials that had used 5-FU/leucovorin schedules over the prior decade. This analysis confirmed that 60-day ACM regularly was encountered at a rate of 5% to 8% in the treatment of metastatic CRC.³⁵³ Thus the 60-day ACM for the IFL regimen was actually *lower* on N9741 than in previous trials and was *lower* than what had been seen consistently with 5-FU/leucovorin regimens alone. In the final analysis of N9741, the 60-day ACM seen in the IFL, FOLFOX-4, and IROX arms were 4.5%, 2.6%, and 2.7%, respectively, and these differences were not statistically significant.

The efficacy results of N9741, however, were statistically significant and showed superior outcome for the patients randomized to FOLFOX-4, as compared to those randomized to either IFL or IROX, in terms of response rate, time to tumor progression, and overall survival (Table 57.14).³⁵⁴ Toxicity for FOLFOX-4 was also superior for virtually all parameters, except of course neurotoxicity. The results of the IROX arm did not statistically significantly differ from those of the IFL arm in terms of toxicity, response, or time to tumor progression; however, survival was borderline statistically significantly better in the IROX arm than the IFL arm ($p = 0.04$).

TABLE 57.14

Results of Intergroup Trial N9741: Irinotecan Plus Bolus 5-Fluorouracil/Leucovorin, Oxaliplatin Plus Infusional 5-Fluorouracil/Leucovorin, and Irinotecan Plus Oxaliplatin in First-Line Treatment of Patients with Metastatic Colorectal Cancer

	IFL (n = 264)	FOLFOX-4 (n = 267)	IROX (n = 264)	P Value (IFL vs. FOLFOX)
Major objective response rate (partial plus complete responses)	31%	45%	35%	0.03
Time to tumor progression	6.9 mo	8.7 mo	6.5 mo	0.001
Overall survival	15.0 mo	19.5 mo	17.4 mo	0.0001
Received second-line therapy with active drug not included in first-line regimen	24% (oxaliplatin)	60% (irinotecan)	50% (fluorouracil)	Not given
Grade 3–4 neutropenia	40%	50%	36%	0.35
Neutropenic fever	15%	4%	11%	0.001
Grade 3–4 diarrhea	28%	12%	24%	0.001
Grade 3–4 nausea	16%	6%	19%	0.001
Grade 3 neuropathy	3%	18%	7%	0.001
60-d all cause mortality	4.5%	2.6%	2.7%	Not significant

IFL, 5-fluorouracil, leucovorin; FOLFOX4, oxaliplatin plus infusional 5-fluorouracil/leucovorin; IROX, irinotecan plus oxaliplatin

From Goldberg RM, Sargent DJ, Morton RF, et al. A randomized controlled trial of fluorouracil plus leucovorin, irinotecan, and oxaliplatin combinations in patients with previously untreated metastatic colorectal cancer. *J Clin Oncol* 2004;22:23–30.

Taken together, where do these trials leave us in terms of first-line use of oxaliplatin- and irinotecan-based regimens? Data from trial N9741 indicate that FOLFOX-4 is superior to IFL in both response rate and time to tumor progression. Overall survival was superior in the FOLFOX-4 arm versus IFL as well; however, interpretation of the survival results of N9741 is somewhat complicated due to imbalances between arms in availability of effective second-line therapy. Second-line CPT-11 was available to all patients who had received FOLFOX-4. Oxaliplatin, however, was not commercially available in the United States during the course of N9741. To what degree this imbalance in second-line therapy may have influenced the survival result is unknown. Also, as IFL contains bolus 5-FU, while FOLFOX-4 contains infusional leucovorin/5-FU2, it is difficult to isolate the irinotecan versus oxaliplatin component from the 5-FU bolus versus 5-FU infusion component.

Two other trials indicate that the FOLFOX and FOLFIRI regimens have similar safety and efficacy, with differing toxicity profiles.^{349,351} Thus, FOLFOX has comparable efficacy to FOLFIRI, whereas FOLFOX has a superior response rate, time to tumor progression, and possibly some degree of survival benefit over IFL. Toxicity with irinotecan-based regimens shows a higher degree of alopecia. Diarrhea and neutropenia are increased on the bolus 5-FU schedule but are similar between FOLFOX and FOLFIRI. Oxaliplatin-based regimens, however, have neurotoxicity, absent from the irinotecan-based regimens, which can be problematic in some patients. It would therefore seem reasonable at this time to favor the use of a high-dose intermittent infusional 5-FU/leucovorin schedule plus either oxaliplatin (i.e., FOLFOX) or CPT-11 (i.e., FOLFIRI). Data do not support continued routine use of the bolus IFL schedule, nor are there randomized data to support the routine use of a bolus 5-FU/leucovorin schedule with oxaliplatin in the metastatic setting. Routine use of IROX is also not supported by the currently available body of data.

Whether to use an irinotecan-based or oxaliplatin-based combination in first-line treatment of good performance status patients can be considered a matter of patient preference, and discussion of the differing toxicity profiles is appropriate to help individuals decide. It is hoped that in the near-term future molecular prognostic indicators and pharmacogenomics will provide useful guidance for the individualization of therapies, but such approaches remain investigational at this time.

The only oxaliplatin schedule registered for use in the United States is FOLFOX-4; however, the modified FOLFOX-6 would appear at this time to be a very reasonable schedule for routine clinical use when the decision is made to use an oxaliplatin/5-FU combination.

The recognition of neurotoxicity as a major limitation of the FOLFOX regimens led to the investigation of optimization of oxaliplatin (the OPTIMOX study).³⁵⁵ In this trial, patients were randomly assigned to receive either standard FOLFOX-4 until progression or 12 weeks of FOLFOX-7, followed by planned cessation of oxaliplatin and continuation of the LV5FU2. As designed, the study called for a reintroduction of oxaliplatin after 6 months of LV5FU2, although this actually occurred in the minority of patients and outcomes were superior in those patients in whom reintroduction of oxaliplatin occurred.³⁵⁶ The primary end point was duration of disease control, the time from initiation of treatment until either progression through all agents (including failure after reintroduction of oxaliplatin if this was done), or death. Duration of disease control as well as progression-free survival and overall survival were not statistically significantly different between the two arms. As anticipated, toxicity, including neurotoxicity, was substantially reduced in the OPTIMOX arm. This OPTIMOX strategy of planned interruption of oxaliplatin can be considered a standard care option in metastatic disease. It is important to discuss plans for such planned interruptions with patients at the beginning of therapy so that they will not be surprised or alarmed at the removal of one of the drugs.

Although a regimen of oxaliplatin, weekly bolus 5-FU, and low-dose weekly leucovorin (bFOL) appeared promising in an initial phase 2 trial, two sequential randomized phase 2 trials, known as TREE-1 and TREE-2, suggest modestly inferior activity for the bFOL schedule compared with FOLFOX or Cape/Ox.^{357,358} Thus, in the metastatic setting, oxaliplatin with bolus 5-FU schedules is therefore not recommended for routine use.

Use of planned sequential administration of FOLFOX and FOLFIRI has also been proposed, both in terms of pretreatment for potentially resectable patients with liver metastases and in terms of adjuvant treatment of earlier stage disease. Several groups are also exploring the use of “triple therapy” with oxaliplatin, CPT-11, and 5-FU/leucovorin (FOLFOXIRI). A randomized phase 3 trial conducted in Italy reported that FOLFOXIRI is tolerable and offers a modest survival benefit over FOLFIRI. These trials utilized higher doses of 5-FU than are likely to be tolerable by American patients, and use of this combination has not gained widespread acceptance.³⁵⁹

As discussed previously, a trial comparing FOLFIRI to capecitabine/irinotecan suggested inferior outcome for the capecitabine-containing regimen.³³⁴ However, a large randomized trial has now compared Cape/Ox versus FOLFOX. The study also had a two-by-two randomization to with or without bevacizumab (discussed subsequently). This trial demonstrated the Cape/Ox regimen to be noninferior to FOLFOX, and each had acceptable toxicity, indicating that Cape/Ox is an acceptable alternative to FOLFOX.³⁶⁰ It should be noted that the Cape/Ox regimen requires a motivated, reliable patient who will be able to take multiple pills of oral medication on a complex schedule, even in the setting of potentially emetogenic oxaliplatin.

Duration of Therapy

Controversy continues to exist regarding the optimal duration of chemotherapy for palliation of metastatic disease. Traditional practice for many years had been to continue chemotherapy until either unacceptable toxicity, clinical deterioration, or disease progression. When efficacy of treatment was more limited, with the duration of therapy typically limited to a small number of months, the issue of treatment breaks did not seem relevant. Now, with patients typically living multiple years with metastatic CRC and with some treatments maintaining control for more extended periods of time, the need for patients to have breaks (often referred to as “treatment holidays” or “chemotherapy-free intervals” [CFI]) is greater, and there is considerable interest in using these approaches. Both physically and psychologically, many patients appear to both need and derive benefit from these treatment interruptions.

The concept of noncontinuous chemotherapy has been investigated for some time now. Maughan et al.³⁶¹ conducted a randomized trial of continuous versus interrupted treatment in 354 patients who were responding or who had stable disease after receiving 12 weeks of either 5-FU- or raltitrexed-based chemotherapy. Patients were randomized to either continue chemotherapy until progression or to stop chemotherapy after the first 12 weeks, followed by a planned restarting on the same chemotherapy at the time of progression. At randomization, 41% of patients had achieved a major objective response and 59% had stable disease. There was no evidence of a difference in overall survival, the primary end point, between the two groups, with an HR of 0.87 ($p = 0.23$, favoring the intermittent arm).

More recently, the idea of planned early cessation of all chemotherapy was investigated in the OPTIMOX-2 trial.³⁶² A total of 202 patients with previously untreated metastatic CRC were treated. All patients received six cycles of modified FOLFOX-7 followed by either continued LV5FU2 until progression, or a complete cessation of all chemotherapy (a CFI). Patients on both arms were planned to receive retreatment with FOLFOX following tumor progression. The results of this study did not support the use of this

planned, early interruption in therapy, as the median duration of disease control, progression-free survival, and overall survival were all inferior in the arm with the early planned CFI. This should not be misconstrued as evidence that CFIs are contraindicated, but rather that early planned CFIs for all patients is not an appropriate strategy. The authors suggest that this study indicates there are no pretreatment parameters that can identify a priori those patients who can successfully benefit from a CFI. Thus, specific decisions regarding use and timing of CFIs cannot be made in advance of starting treatment; rather, clinical judgment must be exercised in deciding on treatment interruptions for CFIs in responding patients after a favorable response. In a retrospective review of 822 patients in the two OPTIMOX studies, after excluding those patients who had early progression within the first 3 months of treatment as well as those who underwent complete gross resection of metastatic disease within 3 months of stopping chemotherapy, Perez-Staub et al.³⁶³ noted that there was no indication of a detriment in survival when comparing those patients who took a CFI versus those who did not. In fact, in this retrospective, nonrandomized analysis, the median survival was 37.5 months in patients who had a CFI versus 21.2 months in matched patients who did not have a CFI. Of note, median overall survival of patients who stopped chemotherapy earlier than 3 months was 24 months, whereas it was 42 months when a CFI was taken between 3 and 9 months into therapy, and 44 months when a CFI was taken later than 9 months into chemotherapy. These studies were accomplished prior to the use of bevacizumab. Some clinicians have advocated the continuation of bevacizumab during CFIs. Such an approach is not supported by data, and given the absence of activity of single-agent bevacizumab in CRC, use of single-agent bevacizumab during otherwise CFIs is not recommended at this time.

Other investigators specifically addressed the question of whether rechallenge with 5-FU after a planned treatment interruption could produce a response. A pooled analysis was conducted on 613 patients involved in three randomized trials of first-line 5-FU-based therapy.³⁶⁴ All patients had a planned maximum treatment period of 6 months. Patients with responding or stable disease at the end of that period were observed off treatment with a plan for retreatment at the time of disease progression. Median time to rechallenge was 11.7 months. Seventeen percent of patients had an objective response to rechallenging. Median survival for the group was 14.8 months. These nonrandomized data indicate that patients have a meaningful response rate at time of reinstitution of chemotherapy.

A similar approach was explored in patients who received second-line irinotecan therapy.³⁶⁵ A total of 333 patients entered into a trial to receive 24 weeks of irinotecan. Patients who remained in the study at the end of that time were to be randomized to either continue treatment or to stop therapy. Of the 333 patients, most came off the study due to progression or toxicity before reaching the 24-week mark. Fifty-five patients with responding or stable disease agreed to randomization. Although the numbers available for comparison were small, there were no differences between the

arms in progression-free survival or overall survival, nor were there differences in quality-of-life scores.

Overall, there appears to be no compelling evidence that continuation of chemotherapy indefinitely is necessary for optimal control of metastatic disease. The option of discontinuation of therapy after a reasonable period of time appears to be an appropriate consideration in standard practice.

Combination versus Single-Agent Chemotherapy

Given that combination regimens are invariably associated with more toxicity than single agents, the question of the need for universal upfront use of these combinations was investigated. The CAIRO (Capecitabine, Irinotecan, Oxaliplatin) trial randomized 820 patients to sequential versus concurrent therapies (Table 57.15).³⁶⁶ In the sequential arm, first-line therapy was single-agent capecitabine. Upon failure, single-agent irinotecan was used, and then third-line therapy was Cape/Ox (since single-agent oxaliplatin is essentially inactive in 5-FU-refractory CRC). The combination arm used Cape/Ox as first-line therapy and capecitabine and irinotecan as second-line therapy. The primary end point, median overall survival, was not statistically significantly different between the two arms (17.4 months for combination versus 16.3 months for the sequential arm; $p = 0.33$). Dose-limiting toxicity (grade 3 or 4) was not significantly different between the two groups; in fact, grade 3 hand-foot syndrome was somewhat more common in the sequential arm (13% versus 7%; $p = 0.004$).

Similar findings were reported in the FOCUS study.³⁶⁷ In this trial, a total of 2,135 patients were randomized to one of three arms. Arm A was sequential therapy, with initial treatment given with 5-FU on the leucovorin/5-FU2 (biweekly infusional) schedule until progression, at which point second-line therapy was given with single-agent irinotecan. Arm B also gave biweekly LV5FU2 until failure, and then LV5FU2 was continued with the addition of either oxaliplatin or irinotecan (this was a second randomization within this arm). Thus, second-line therapy was a change from biweekly LV5FU2 to either FOLFOX or FOLFIRI in this arm. In arm C, patients began with combination chemotherapy, and within this arm were randomized to either FOLFOX or FOLFIRI. The primary end point, median overall survival, for arm A was 13.9 months. For arm B, survival was 15.0 months for irinotecan and 15.2 months for oxaliplatin. Arm C had a median overall survival of 16.7 months for the FOLFIRI patients and 15.4 months for those treated with FOLFOX. Only the difference between arm A and the irinotecan arm of arm C reached statistical significance ($p = 0.01$). Arm B (initial LV5FU2 followed by FOLFOX or FOLFIRI) was noninferior to arm C (initial FOLFOX or FOLFIRI) (HR = 1.06; 90% CI = 0.97 to 1.17).

Taken together, the CAIRO and FOCUS trials provide a strong argument that not all patients with unresectable metastatic disease require exposure to the toxicity of combination therapy, and

TABLE 57.16A

Efficacy Outcomes, First-Line Treatment of Metastatic Colorectal Cancer: Irinotecan Plus Bolus 5-Fluorouracil/Leucovorin Plus Placebo Versus 5-Fluorouracil/Leucovorin Plus Bevacizumab

Regimen	No. of Patients	Response Rate	Progression-Free Survival	Overall Survival
IFL + placebo	411	34.8%	6.2 mo	15.6 mo
IFL + bevacizumab	402	44.8% $p = 0.004$	10.6 mo $p < 0.001$	20.3 mo $p < 0.001$

IFL, 5-fluorouracil, leucovorin.

that initial use of fluorinated pyrimidine alone in patients with previously untreated metastatic CRC is a treatment alternative that needs to be carefully considered.

Bevacizumab

Bevacizumab is a humanized monoclonal antibody that binds to VEGF, thereby substantially reducing the amount of circulating ligand and thus preventing receptor activation.^{368,369} The first trial of bevacizumab in CRC was a modest-sized, three-arm, randomized phase 2 trial in which a total of 104 patients were randomly assigned to either one of two different doses levels of bevacizumab (5 mg/kg or 10 mg/kg) plus weekly 5-FU/leucovorin or to 5-FU/leucovorin alone.³⁷⁰ The response rate, time to tumor progression, and overall survival were superior in the 5-FU/leucovorin with 5 mg/kg bevacizumab arm. Despite the small size and limited statistical power of this study, this result would served as the basis for design of the pivotal phase 3 trial of bevacizumab in CRC.

The initial design of the phase 3 pivotal trial was a comparison between 5-FU/leucovorin plus placebo to 5-FU/leucovorin plus 5 mg/kg of bevacizumab. However, as the randomized phase 2 trial, discussed previously, was nearing completion, the randomized phase 3 trial was reported, which demonstrated a modest but statistically significant survival advantage for the IFL regimen (irinotecan plus weekly bolus 5-FU/leucovorin) compared with 5-FU/leucovorin alone.³⁴⁷ As a result of this trial, the IFL regimen was then felt to be the appropriate control arm for subsequent phase 3 trials. There were no safety data at the time, however, on the combination of bevacizumab plus IFL. As a result of this, a three-arm trial was designed that contained (1) 5-FU/leucovorin/bevacizumab, (2) IFL/bevacizumab, and (3) IFL/placebo (the control arm).³⁷¹ The design included a preplanned analysis of safety on all arms when enrollment reached 100 patients per arm, with a further plan to close the 5-FU/leucovorin/bevacizumab arm at that time if the safety data indicated acceptable tolerability and safety of the IFL/bevacizumab arm.

In the final efficacy analysis, the IFL/bevacizumab cohort experienced superior outcome compared to the IFL/placebo group in response rate (45% versus 35%; $p < 0.003$), progression-free survival (10.6 months versus 6.2 months; $p < 0.00001$), and overall survival (20.3 months versus 15.6 months; $p = 0.00003$) (Table 57.16A).

It should be noted that no crossover to second-line bevacizumab in the IFL/placebo control arm was allowed in this trial.

In order to better understand the effects of bevacizumab in conjunction with 5-FU/leucovorin, Kabbinar et al.³⁷² combined the data from three separate modest-sized trials to create a more robust data set. In this combined analysis of 5-FU/leucovorin with or without bevacizumab, there was a statistically significant survival advantage for the patients who received bevacizumab. Given the favorable aspects of the biweekly infusional LV5FU2 schedule used in the FOCUS trial, the LV5FU2 schedule would seem most appropriate for combination with bevacizumab.³⁷³ At the same time as the pivotal front-line study was accruing, the Eastern Cooperative Oncology Group (ECOG) also performed a trial (ECOG-3200) to evaluate the use of bevacizumab in the second-line setting.³⁷⁴ This trial randomized patients who had failed irinotecan and 5-FU but were naive to bevacizumab, to one of three arms: bevacizumab/FOLFOX, FOLFOX alone, or bevacizumab. The investigators chose to investigate a 10 mg/kg bevacizumab dose. Overall, a modest but statistically significant improvement in median overall survival was demonstrated for FOLFOX-4 with bevacizumab versus FOLFOX-4 alone (12.5 months versus 10.7 months; $p = 0.0024$), and grade 3 or 4 toxicities were not increased. The bevacizumab-alone arm had substantially inferior progression-free survival and an investigator-adjudicated response rate of 3%, suggesting that single-agent bevacizumab does not have meaningful activity in CRC and should not be used. It is important to note that this trial was performed *exclusively* in patients who had *not* received bevacizumab in the first-line setting. This trial provides no data on whether use of bevacizumab with a second-line regimen after progression on a first-line bevacizumab-containing regimen is efficacious.

Although it was performed in second-line patients, the ECOG-3200 trial was the first trial to provide safety data for the combination of bevacizumab plus FOLFOX. As a result of this, even before front-line data were available, bevacizumab plus FOLFOX had become widely accepted as a front-line option in the United States for metastatic CRC. More recently, the NO16966 trial directly addressed the question of front-line bevacizumab plus oxaliplatin-based therapy (Table 57.16B).³⁷⁵ In this trial, 1,400 patients with previously untreated CRC were randomly assigned to

TABLE 57.16B

Efficacy Outcomes, First-Line Treatment of Metastatic Colorectal Cancer: Capeox/Folfox Plus Placebo Versus Capeox/Folfox Plus Bevacizumab

Regimen	No. of Patients	Response Rate	Progression-Free Survival	Overall Survival
CapeOx/FOLFOX + placebo	701	49%	8.0 mo	19.9 mo
CapeOx/FOLFOX + bevacizumab	699	47% $p = 0.31$	9.4 mo $p = 0.0023$	21.3 mo $p = 0.078$

CapeOx, capecitabine, oxaliplatin; FOLFOX, fluorouracil, leucovorin, oxaliplatin.

From Saltz LB, Clarke S, Diaz-Rubio E, et al. Bevacizumab in combination with oxaliplatin-based chemotherapy as first-line therapy in metastatic colorectal cancer: a randomized phase III study. *J Clin Oncol* 2008;26:2013-2019.

either FOLFOX-4 or Cape/Ox and then to either placebo or bevacizumab, in a two-by-two randomization. Although the study did show a statistically significant progression-free survival advantage for the addition of bevacizumab (9.4 months versus 8.0 months for chemotherapy with bevacizumab versus chemotherapy with placebo, respectively; HR = 0.83; $p = 0.003$), this difference was more modest than the 4.4-month progression-free survival difference seen in the initial bevacizumab with IFL front-line trial. Overall survival improvement with bevacizumab approached, but did not reach, statistical significance (21.3 months versus 19.9 months; HR = 0.89; $p = 0.077$). Also, in the NO16966 trial, the addition of bevacizumab to front-line oxaliplatin-based chemotherapy did not confer any response benefit. It is noteworthy that the majority of patients on this trial discontinued treatment, presumably due to nonbevacizumab-related toxicity issues, before progression. This may have diminished the impact of bevacizumab on survival and progression-free survival but would not have impacted the response rate.

Toxicity

In terms of toxicity, grade 3 hypertension was higher in the bevacizumab/IFL arm than in the placebo/IFL arm (11% versus 2%) in the IFL/bevacizumab study.³⁷¹ Hypertension is now widely recognized as a common side effect of bevacizumab, and monitoring for and treatment of hypertension with antihypertensive medications is a routine part of bevacizumab management. Incidences of overall thromboembolic events and proteinuria were not statistically different between the two arms. However, two rare but extremely serious toxicities were encountered with increased frequency in the bevacizumab-containing arm: GI perforations and arterial thrombotic events.

The GI perforations were a group of events that included a perforated gastric ulcer, small bowel perforations, and free air under the diaphragm without identified sources. Although these were somewhat heterogeneous in nature, it was noted that six such events occurred on the bevacizumab-containing arm (one fatal) compared with none on the chemotherapy-alone arm. No clear risk factors for these perforations could be identified from this trial. Interestingly, GI perforations were not frequent occurrences in large cooperative group trials in patients with lung cancer or breast cancer; however, an unusually high GI perforation rate has recently halted accrual on a trial of bevacizumab in patients with ovarian cancer. These ovarian observations illustrate an important aspect about GI perforations in association with bevacizumab: there is not an association between the presence of an intact primary tumor in the colon and a GI perforation. Concerns have been expressed by some clinicians about the possibility of needing to remove an asymptomatic primary colorectal tumor in a patient with synchronous stage IV disease before using bevacizumab out of an unsubstantiated fear that the primary will put the patient at risk for perforation. At present, there are no data to support this assumption, and surgery for an asymptomatic primary tumor in a stage IV patient is not routinely indicated, regardless of whether there are plans to use a bevacizumab-containing chemotherapy regimen.³¹⁹

The other rare but very serious identified increased risk with bevacizumab-containing treatment was that of arterial thrombotic events. Initially, no clear indication of this risk was detected in the pivotal phase 3 trial. However, in a combined analysis of several trials, an important observation was made. Here again, multiple events were combined into one metric. Thus, cerebral vascular accidents, myocardial infarctions, transient ischemic attacks, and angina were combined to create the metric of arterial thrombotic events. The observed incidence of these events was 2.5% in the nonbevacizumab-containing control arms versus 5.0% in the bevacizumab-containing experimental arms. It was noted that patients who had histories of cardiovascular or atherosclerotic disease appeared to be at greater risk for increased bevacizumab-related arterial thrombotic complications. In addition, a further

analysis of these events suggested that the risk was essentially linear over time, indicating that the risk of a new arterial thrombotic event was the same in earlier versus later months of exposure.³⁷⁶

Another complication of bevacizumab that has been rarely described in the literature is fistula formation. Ganapathi et al.³⁷⁷ reports a 4.1% incidence of this problem in a review of 222 patients with metastatic CRC. Two-thirds were perineal or anal with the remainder colovesicular, occurring an average of 3.9 months after initiation of treatment. Cessation of bevacizumab led to fistula healing in nearly all cases; however, three patients required fecal diversion. The authors suggest that this complication has been underreported thus far and stress the importance of early recognition.³⁷⁷

Bevacizumab Beyond Progression

Prior studies had demonstrated the activity of bevacizumab when added to first-line chemotherapy, and the ECOG 3200 trial had shown that bevacizumab added to second-line chemotherapy in bevacizumab-naïve patients. Until recently, however, data were lacking regarding the question of continuation of bevacizumab with second-line therapy after progression of disease through a first-line, bevacizumab-containing regimen. This question has now been addressed by the TML trial.³⁷⁸ In this trial, 820 patients who had progressed through a first-line, bevacizumab-containing regimen were assigned to a noncross-resistant chemotherapy regimen (irinotecan plus fluoropyrimidine if previously treated with oxaliplatin or oxaliplatin-fluoropyrimidine if previously treated with irinotecan) and then randomized to receive bevacizumab with this second-line chemotherapy or not. The arm receiving bevacizumab showed a modest but statistically significant survival benefit of 1.4 months (overall survival of 11.2 months versus 9.8 months; HR = 0.81; 95% CI = 0.69 to 0.94; $p = 0.0062$). Grade 3 to 5 bleeding or hemorrhage (8 [2%] versus 1 [1%]), GI perforation (7 [2%] versus 3 [1%]), and venous thromboembolisms (19 [5%] versus 12 [3%]) were more common in the bevacizumab plus chemotherapy group than in the chemotherapy-alone group.

Aflibercept

Aflibercept is a fusion molecule containing the binding domains of VEGF receptors 1 and 2 bound to the human immunoglobulin (Ig) G Fc fragment, forming a VEGF trap molecule. Aflibercept binds all human VEGF A isoforms, VEGF B, and placental growth factor with greater affinity than the native receptors for these ligands. Aflibercept has been evaluated in the large scale phase 3 VELOUR trial, in which 1,226 patients who had progressed on a first-line oxaliplatin-containing regimen were randomized to receive second-line FOLFIRI plus aflibercept 4 mg/kg versus FOLFIRI plus placebo. All treatments were given every 2 weeks. Thirty percent of patients had received prior bevacizumab with their first-line treatment regimen, while the remainder were naïve to anti-VEGF therapy. The group receiving aflibercept achieved a modest, but statistically significant overall survival benefit of 1.4 months (13.50 months versus 12.06 months; HR = 0.817; 95% CI = 0.713 to 0.937; $p = 0.0032$).³⁷⁹ PFS was also statistically significantly improved from 4.67 months to 6.9 months with the addition of aflibercept ($p < 0.0001$). Response rate was improved from 11.1% to 19.8%.

The findings of the VELOUR and TML trials show striking similarities to one another. Each utilized an anti-VEGF strategy in second-line treatment in conjunction with active chemotherapy, and each shows a 1.4-month survival benefit. Given these findings, use of either with second-line FOLFIRI (if second-line FOLFIRI is deemed appropriate) would seem reasonable. Aflibercept has not demonstrated benefit in conjunction with oxaliplatin-based regimens at the time of this writing, and so use of aflibercept with oxaliplatin-based chemotherapy is not recommended. Furthermore, a change from FOLFIRI-aflibercept to

FOLFIRI-bevacizumab (or vice versa) is not supported by current data, nor is use of either aflibercept or bevacizumab as a single agent. As such, aflibercept presents an option for second-line therapy in conjunction with FOLFIRI, but does not create a new line of therapy in the continuum of treatment.

Regorafenib

Regorafenib is a small molecule multitargeted tyrosine kinase inhibitor. It is closely related to its parent compound, sorafenib, and differs only by the addition of a fluorine atom. After phase 1 trials identified preliminary evidence of activity in patients with refractory CRC, a large phase 3 trial of regorafenib versus placebo was undertaken.³⁸⁰ A total of 760 patients, all with ECOG grade 0 or 1 performance status, who had progressed through all standard therapies, were randomized 2:1 to received regorafenib 160 mg orally daily versus placebo. The regorafenib group achieved a modest but statistically significant overall survival benefit of 1.4 months (6.4 months versus 5.0 months; HR = 0.77; 95% CI = 0.64 to 0.94; $p = 0.0052$). Response was essentially nonevident, with a response rate of 1% in the regorafenib arm. Grade 3 hand-foot syndrome (17%) and grade 3 fatigue (10%) were the most common toxicities encountered on the regorafenib arm. Regorafenib monotherapy can be considered as a standard care option for good performance status patients who have progressed through standard therapies. Studies assessing the use of regorafenib in earlier lines of therapy and in combination with cytotoxic agents are in progress at the time of this writing.

Cetuximab and Panitumumab

The EGFR, also called HER-1, is a transmembrane glycoprotein receptor. When the external binding domain of the EGFR binds specific ligands, such as epidermal growth factor or TGF- α , receptor dimerization occurs (either homodimerization with another EGFR or heterodimerization with another member of the EGFR family). This in turn stimulates phosphorylation of the tyrosine kinases on the intracellular domain of the receptor, which initiates a signaling cascade, which ultimately regulates cell proliferation, migration, adhesion, differentiation, and survival.^{381–385} Cetuximab (c-mab), is a chimeric IgG₁ monoclonal antibody that recognizes and binds to the extracellular domain of the EGFR. Panitumumab (p-mab) is a fully human IgG₂ monoclonal antibody that also targets the EGFR. Binding of either c-mab or p-mab to this receptor does not cause receptor activation, but rather results in a steric interference with the ligand binding site.³⁸⁴

Preclinical models of cetuximab, or its murine precursor, demonstrated more substantial activity when given in combination with cytotoxic chemotherapy. Based on these observations, and on a single anecdotal report of a major response to cetuximab plus irinotecan in a young woman with irinotecan-refractory CRC, a multicenter phase 2 trial was initiated. This trial, reported in abstract

form only, was conducted in patients who were determined by their treating investigator to have progressed on irinotecan.³⁸⁵ Patients were treated with cetuximab at a dose of 400 mg/m² loading dose week 1 over 2 hours, followed by weekly 250 mg/m² over 1 hour. Irinotecan was given on the same dose and schedule as had previously failed. Irinotecan dose reductions made previously, prior to study entry, were maintained upon initiation of the study treatment.

One hundred twenty patients with irinotecan-refractory CRC were identified and enrolled. In addition, in a parallel portion of the trial, 28 patients with clinically and radiographically stable disease after receiving a minimum of 3 months of irinotecan therapy were also enrolled and treated by the addition of cetuximab to their ongoing irinotecan therapy. The response outcome of this “stable disease cohort” was not reported; only those patients who were felt to be irinotecan refractory were included in the initial report. As reported by an independent response assessment committee, 22.5% of irinotecan-refractory patients achieved a major objective response. The irinotecan-related toxicity was relatively mild in this population, at least in part because many patients had already had irinotecan dose modifications made prior to starting on this trial. Of the side effects specifically attributable to cetuximab, 3% of patients developed an allergic, anaphylactoid reaction requiring discontinuation of cetuximab therapy, and 75% of patients experienced a skin rash (12% grade 3), a rash now recognized to be characteristic of all EGFR inhibitors. This rash superficially resembles acne, leading to its initial description as an acneiform rash. However, microscopically this is not acne, and topical acne medications are ineffective in its management. An interesting observation from this trial, which has since been corroborated in multiple trials, is that the presence and severity of the rash appeared to be associated with response in this study.

The results seen in the phase 2 cetuximab plus irinotecan combination trial raised the question, both from a scientific and from a regulatory perspective, of the activity of single-agent cetuximab in irinotecan-refractory CRC. A small phase 2 trial was therefore quickly designed and accrued. In this trial, 5 of 57 patients (9%) achieved a partial response confirmed by an independent radiologic review.³⁸⁶

Based on the preliminary results of the initial phase 2 cetuximab plus irinotecan study, described previously, a subsequent larger trial, ultimately reported by Cunningham et al.,²⁴⁵ was designed to provide confirmatory evidence of the activity of cetuximab in CRC (Table 57.17). This large, randomized phase 2 trial in patients with irinotecan-refractory CRC, which has become known as the BOND trial, compared cetuximab plus irinotecan to cetuximab monotherapy. A total of 329 patients were randomized in a two-to-one schema. The response rates of 22.9% for cetuximab plus irinotecan and 10.8% for cetuximab alone were virtually identical to the response rates that had been reported previously in the two US phase 2 trials, confirming the activity of this agent in CRC. Time to tumor progression in the Cunningham et al.²⁴⁵ study was

TABLE 57.17

Efficacy Outcomes: Cetuximab Plus Irinotecan Versus Cetuximab Alone in Irinotecan-Refractory Colorectal Cancer

	No. of Patients	Response Rate (95% CI)	Disease Control (95% CI)	Median TTP (mo)	Median OS (mo) (95% CI)
Cetuximab	111	11% (6%–18%)	32% (24%–42%)	1.5	6.9 (5.6–9.1)
Cetuximab + irinotecan	218	23% (18%–29) ^a	56% (49%–62%) ^b	4.1 ^c	8.6 (7.6–9.6)

CI, confidence interval; TTP, time to progression; OS, overall survival.

^a $p = 0.0074$.

^b $p = 0.0001$.

^c $p < 0.0001$.

From Cunningham D, Humblet Y, Siena S, et al. Cetuximab monotherapy and cetuximab plus irinotecan in irinotecan-refractory metastatic colorectal cancer. *N Engl J Med* 2004;351:337–345.

4.1 months for the combination versus 1.5 months for single-agent cetuximab. Survival in the two arms was not significantly different; however, the study was neither designed nor powered to address the issue of a survival advantage for cetuximab, and cetuximab was given to all patients on both arms of the study.

A National Cancer Institute Canada phase 3 trial compared cetuximab plus best supportive care to best supportive care alone in 572 patients who had exhausted standard treatment options.³⁸⁷ The median overall survival was improved by 1.5 months (from 4.6 months to 6.1 months) in the cetuximab group compared to supportive care alone. Partial responses occurred in 23 patients (8.0%) in the cetuximab group versus none in the supportive care group ($p < 0.001$).

Similar results were reported with panitumumab. As seen with single-agent cetuximab, phase 2 evaluations of panitumumab in patients with CRC indicate approximately a 10% response rate, with over 90% of patients experiencing some degree of acneiform-like rash.^{388,389} The fully human nature of this antibody appears to reduce the likelihood of anaphylactoid infusion reactions, with only 1 of the 148 patients treated after experiencing a dose-limiting allergic reaction. A randomized trial of panitumumab versus best supportive care in the salvage setting demonstrated a modest (8 weeks versus 7.3 weeks) but highly statistically significant improvement in median progression-free survival for single-agent panitumumab over best supportive care (HR = 0.54; $p < 0.000000001$). Response rate to p-mab was 10%. There was no difference in overall survival; however, there was extensive postprogression crossover, which obscures this end point.³⁹⁰

KRAS and Other Determinants of Anti-Epidermal Growth Factor Receptor Resistance

Perhaps the most important development in the use of anti-EGFR agents over the past several years has been the recognition that these agents only have the potential to be beneficial to patients whose tumors have nonmutated, or wild-type, KRAS gene. KRAS is a signal transduction protein that is a critical intermediate in transmission of growth and survival signals from the EGFR to the nucleus. Mutations in exon 2 of the gene that encodes for the KRAS protein lead to constitutive activation of this signaling pathway, which renders blocking of the EGFR-binding site on the surface useless. Several small retrospective series identified KRAS mutations as being incompatible with responses to cetuximab.^{391,392} Subsequently, Amado et al.³⁹³ demonstrated that the activity of panitumumab in the registration study referenced previously was limited to those patients with wild-type KRAS. In this trial, 92% of patients had tissue available for KRAS genotyping, and 43% of tumors were found to harbor a mutation in codons 12 or 13 in exon 2 of KRAS. The objective response rate to single-agent panitumumab was 17% in KRAS wild-type tumors and 0% in those tumors that had a KRAS

mutation. The progression-free survival in the patients with KRAS wild-type tumor who received panitumumab was 12.3 weeks versus 7.3 weeks for best supportive care. In patients with KRAS-mutated tumors, there was no difference in progression-free survival with panitumumab versus best supportive care. Again, overall survival in this trial could not be interpreted due to extensive postprogression crossover.

Similarly, analysis of the National Cancer Institute Canada study, discussed previously, demonstrated that activity of cetuximab as a single agent in chemotherapy-refractory disease was limited to the KRAS wild-type patients only (Table 57.18).³⁹⁴ Approximately 70% of patients in this trial had tissue available for KRAS genotyping, and 42% were found to have mutated KRAS. Those with mutated KRAS showed no evidence of clinical benefit from cetuximab, while patients whose tumors had wild-type K-ras showed a 4.7-month improvement in median overall survival with cetuximab versus best supportive care (9.5 months versus 4.8 months; HR for death = 0.55; 95% CI = 0.41 to 0.74; $p < 0.001$). In the control group who received best supportive care, KRAS mutation status had no impact on median overall survival ($p = 0.97$). Although some data have suggested that tumors with KRAS exon 2, codon 13 mutations might still garner some benefit from first-line treatment with cetuximab or panitumumab,³⁹⁵ subsequent data have refuted this, and any KRAS exon 2 mutation remains a firm contraindication to treatment with an EGFR inhibitor. (More recently, a retrospective analysis suggested that in addition to exon 2 KRAS mutations, tumors with mutated BRAF, NRAS, or PIK3CA were significantly associated with a low response rate to cetuximab or panitumumab.³⁹⁶) The question of the impact of other KRAS mutations outside of exon 2 has been further addressed, as has the impact of NRAS mutations. Data strongly suggest that the presence of any KRAS or NRAS mutation confers resistance to cetuximab and panitumumab, and that these agents should not be used in patients whose tumors harbor any of these mutations.¹⁵⁰ The role of BRAF genotyping remains less definitive. While an unpreplanned retrospective subset analysis of a combination of two first-line trials suggests some possible contribution of cetuximab in patients with BRAF-mutated tumors, most published datasets of patients treated in the nonfirst-line setting show essentially no activity for cetuximab or panitumumab in patients with BRAF-mutated tumors.

Genotyping for KRAS mutation status should now be regarded as standard practice in all patients with stage IV disease, and cetuximab and panitumumab should only be considered in patients with nonmutated KRAS.³⁹⁷ Importantly, using a matched set of resected metastases and primary tumors from 84 patients, Vakiani et al.³⁹⁸ demonstrated near-complete concordance between primary and metastasis for RAS, BRAF, and PIK3CA. Therefore, genotyping of the primary tumor is sufficient and patients do not need to be subjected to a biopsy of a metastatic site for the purposes of tissue genotyping.

It is prudent to obtain KRAS genotyping at the time that stage IV disease is diagnosed, not necessarily because the information is needed for first-line therapy, as only a minority of patients will be

TABLE 57.18

Cetuximab Versus Best Supportive Care in Metastatic Chemotherapy-Refractory Colorectal Cancer

	Overall Survival		Progression-Free Survival		Response Rate	
	KRAS Wt	KRAS Mut	KRAS Wt	KRAS Mut	KRAS Wt	KRAS Mut
Cetux	9.5 mo	4.5 mo	3.7 mo	1.8 mo	12.8%	1.2%
BSC	4.8 mo	4.6 mo	1.9 mo	1.8 mo	0%	0%
P value	0.001	0.89	0.001	0.96	NR	NR

Wt, wild type; Mut, mutant; Cetux, cetuximab; BSC, best supportive care; NR, not reported.

appropriate for first-line anti-EGFR therapy, but because whether a patient can consider the use of cetuximab or panitumumab in the course of multiple lines of therapy is easier to both determine and to deal with early on when there are multiple options, rather than waiting until all other options are exhausted. At present, there is no role for determining KRAS status in stage I, II, or III disease, as there is no basis for use of EGFR agents in other than stage IV.

Preliminary data suggests that KRAS status might play a role in oxaliplatin sensitivity as well. In vitro analysis, published by Lin et al.³⁹⁹ demonstrated that this mutation caused downregulation of ERCC1 (excision repair cross-complementation group 1), which led to enhanced oxaliplatin sensitivity. Overexpression of ERCC1 has been shown previously to be associated with resistance to platinum-based therapy in a number of cancers. Improved understanding of this pathway may prove critical toward defining new targets for KRAS-mutant CRC treatment.³⁹⁹

Cetuximab or Panitumumab in First-Line Therapy

A 1,200-patient study of FOLFIRI with or without cetuximab, known as the CRYSTAL trial, has been reported.⁴⁰⁰ The primary end point of the trial, progression-free survival, was statistically significantly improved with the addition of cetuximab, albeit by only 0.9 month, or 27 days. When the study was analyzed in terms of KRAS genotype, those patients with mutated KRAS showed no benefit, while those with wild-type KRAS showed a progression-free survival improvement of 1.2 months, or 37 days, but also a median overall survival improvement from 20.0 months to 23.5 months (HR = 0.796; $p = 0.0093$).⁴⁰¹ Response rates were also statistically significantly higher (57.3% versus 39.7%) in the cetuximab arm for the KRAS wild-type tumors. Skin rash and diarrhea were increased in the cetuximab arm. As has been noted in virtually all trials of anti-EGFR agents, there was a strong correlation between severity of skin rash and clinical benefit, with progression-free survival advantage being limited to those patients with grade 2 or 3 skin rash. BRAF was confirmed as a poor prognostic factor but was not predictive of response to cetuximab in this trial. The numbers of BRAF-mutated tumors limit the power to detect a predictive role of BRAF in this trial, however.

FOLFOX with or without cetuximab had been initially investigated in a randomized phase 2 trial in which the primary end point was response rate.⁴⁰² A total of 337 patients were treated. The overall response rate was improved by the addition of cetuximab from 36% to 46%, a result that did not achieve statistical significance ($p = 0.64$). For the KRAS wild-type patients, however, the result was more robust, with an improvement from 37% to 61% ($p = 0.011$). Progression-free survival was very modestly, albeit statistically significantly improved in the KRAS wild-type patients by a median of 15 days; however, progression-free survival was statistically significantly worse in the cetuximab arm in those patients whose tumors had mutated KRAS.

However, several larger phase 3 trials have cast considerable doubt on the role of cetuximab in conjunction with oxaliplatin-based therapy. In the Medical Research Council COIN trial, 1,603 patients with previously untreated metastatic CRC were treated with oxaliplatin plus a fluoropyrimidine (either the FOLFOX or Cape/Ox regimen) and randomized to receive cetuximab in addition or not. In the patients with KRAS wild-type tumors (367 with cetuximab plus oxaliplatin-containing chemotherapy and 362 with oxaliplatin-containing chemotherapy alone), there was no improvement in overall survival (17.9 months versus 17 months; HR = 1.04; $p = 0.67$) or in progression-free survival (8.6 months versus 8.6 months in the two arms). Overall response rate increased from 57% to 64% with the addition of cetuximab ($p = 0.049$). The data from this trial do not support use of cetuximab with front-line oxaliplatin-based chemotherapy. Outcomes were worse with the addition of cetuximab to capecitabine plus oxaliplatin, and the use of that combination is specifically not recommended.⁴⁰³ In addition, the Nordic VII trial investigated the addition of cetuximab to the Nordic FLOX regimen of oxaliplatin, bolus 5-FU and leucovorin in a 571-patient phase 3 trial.⁴⁰⁴

Patients were randomized to one of three arms: Nordic FLOX given continuously, cetuximab plus Nordic FLOX given continuously, or cetuximab plus Nordic FLOX given intermittently. There were no statistically significant differences in the median progression-free survival between the three arms (7.9 months, 8.3 months, and 7.3 months, respectively). Overall survival also showed no difference between the three arms (20.4 months, 19.7 months, and 20.3 months, respectively). Even in patients with KRAS wild-type tumors, cetuximab did not provide demonstrable benefit.

Taken in the aggregate, the data do not lend substantial support to the use of cetuximab with oxaliplatin-based chemotherapy. Curiously, however, the results with panitumumab are somewhat different. In a phase 3 trial of FOLFOX with or without panitumumab (6 mg/kg every 14 days), 1,183 patients were randomized, of whom 60% had wild-type KRAS.⁴⁰⁵ Progression-free survival was modestly but statistically significantly improved with panitumumab in the KRAS wild-type patients (9.6 months versus 8 months; $p = 0.02$), and response rate was increased from 48% to 55%. However, as was seen with cetuximab, in the patients with KRAS-mutated tumors, the addition of panitumumab resulted in a statistically significant *worsening* of median progression-free survival from 8.8 months in the control arm to 7.3 months in the panitumumab-containing arm. In an updated analysis focusing on KRAS wild-type patients only, as statistically significant survival benefit was seen with the addition of panitumumab in this cohort.¹⁵⁰ The addition of panitumumab resulted in increased skin rash, diarrhea, and hypomagnesemia.

Also reported in abstract form is a phase 3 trial of second-line FOLFIRI with or without panitumumab.⁴⁰⁶ Despite this being a second-line study, patients had an excellent performance status (ECOG 0 or 1 in 94% of patients). KRAS mutations were present in 45% of patients. For the patients with KRAS wild-type tumors, the progression-free survival was statistically significantly improved in the panitumumab-containing arm (5.9 months versus 3.9 months; $p = 0.004$), and response rate was improved as well (35% versus 10%). Overall survival differences in favor of the panitumumab arm (14.5 months versus 12.5 months) did not reach statistical significance ($p = 0.1$). There were no differences in efficacy outcomes with the addition of panitumumab in the patients with KRAS-mutated tumors. Again, skin rash, diarrhea, and hypomagnesemia were increased in the panitumumab arm.

More recently the long-awaited initial results of the NCI cooperative group 80405 study have been reported in abstract form. In this trial, patients with previously untreated metastatic colorectal cancer with wild-type KRAS were enrolled. Patients were assigned to receive either FOLFOX or FOLFIRI per physician preference, and then randomized to receive either cetuximab or bevacizumab. There was no difference in overall survival, the primary study endpoint, between the cetuximab and bevacizumab arms (29.0 months vs 29.9 months, $p = 0.34$).⁴⁰⁷

Toxicities of Anti-Epidermal Growth Factor Receptor Monoclonal Antibodies

The primary toxicity of cetuximab and panitumumab is an acne-like rash, which is seen to some degree in from 75% to 100% of patients treated. This rash is not acne, and it is accompanied by skin dryness and paronychia cracking. Other than moisturizers, which are recommended, no topical agents have been shown to be of benefit in the treatment of this rash. Drying agents and retinoids, such as are used in the treatment of acne, are contraindicated. Anecdotal reports of benefit for topical steroids or antibiotics do not have supportive randomized data, and as the natural history of the rash is to wax and wane, interpretation of these anecdotal reports is problematic. There are data suggesting that prophylactic use of oral antibiotics may somewhat mitigate the severity of the rash.⁴⁰⁸ Importantly, it has been well established that there is a clear correlation between severity of skin rash and favorable outcome with

EGFR agents.⁴⁰⁹ The mechanism of this correlation has not yet been determined; however, it is clear that benefit from these agents is virtually confined to those patients who experience a grade 2 or 3 skin rash. A severe rash does not guarantee a response or clinical benefit; however, absence of a rash after the first month of therapy is virtually incompatible with clinical benefit from these agents. This is an important point to consider, especially in consideration of front-line use; only those patients with a very substantial rash stand a chance of benefit.

Hypersensitivity reactions, which are anaphylactoid in nature and are completely separate and distinct from the skin rash toxicity discussed previously, occur in approximately 3% of patients with cetuximab and <1% of patients with panitumumab. Almost all of these reactions are first-dose events. Dramatic regional differences in the frequency of these reactions have been noted, with serious hypersensitivity reactions to cetuximab noted in up to 20% of patients in North Carolina and Tennessee, while the serious hypersensitivity reaction rate in the northeastern United States is <1%.⁴¹⁰ Subsequently, it has been demonstrated that there is a high prevalence of cetuximab-specific IgE in Tennessee, suggesting cross-reactivity with an environmental allergen.⁴¹¹ Panitumumab does not appear to exhibit this marked regional variation in incidence of hypersensitivity reaction, and would be the clearly preferred agent over cetuximab in these areas of high incidence of cetuximab hypersensitivity.

It should be noted that the incidence of skin rash appears to be quite similar between cetuximab and panitumumab, as does the degree of clinical activity. Thus, outside of the areas that see high frequency of cetuximab hypersensitivity reactions, there appears to be little reason to favor one agent over the other. Case reports and anecdotal evidence suggest that patients who experience hypersensitivity to cetuximab do typically tolerate panitumumab. There is no basis, however, for using one of these agents after clinical failure on the other.

Another more recently recognized toxicity of anti-EGFR therapy is hypomagnesemia.⁴¹² This result is due to hypermagnesemia, presumably promoted by EGFR antagonism in the loop of Henle. Regular monitoring of serum magnesium levels, and intravenous magnesium supplementation, when indicated, should be practiced routinely with anti-EGFR therapies. Oral magnesium is unlikely to provide adequate supplementation, as diarrhea from this is often dose-limiting.

Cetuximab and Panitumumab in Epidermal Growth Factor Receptor–Negative Patients

From the outset of clinical development, the assumption was made that quantitative EGFR expression would be predictive of the activity, or lack thereof, of an anti-EGFR antibody, and that an absence of demonstrable EGFR expression would therefore preclude clinical activity of cetuximab or panitumumab. For this reason, all early trials with these agents required that the patient's tumor shows EGFR positivity by IHC as a criterion for study eligibility. This assumption, that EGFR expression would be predictive, has never been supported by clinical or preclinical data and has been refuted by all clinical data that have addressed the issue. All of the reported cetuximab trials to date, the earlier ones of which excluded EGFR-negative patients altogether, have demonstrated absolutely no correlation between the intensity of the EGFR expression and clinical response.^{245,385} Additionally, the results of a small cohort of nine patients who were EGFR-negative and treated with cetuximab were reported in abstract form.⁴¹³ Two major objective responses were reported by the investigators, one of which was confirmed as a major response by third-party review and one of which was not.

On the basis of the lack of correlation between EGFR staining intensity and response, as well as the small data set outlined previously, a decision was made at Memorial Sloan Kettering Cancer Center in New York that patients with EGFR-negative CRC

would not be excluded from standard off-protocol treatment with cetuximab simply on the basis of EGFR status. Subsequently, a retrospective review was conducted using the computerized pharmacy records to identify all patients who had received non-research cetuximab-based therapy at Memorial Sloan Kettering Cancer Center in the first 3 months of cetuximab's commercial availability. This review identified 16 patients with irinotecan-refractory, EGFR-negative CRC who had been treated. Fourteen of these patients had received cetuximab in combination with irinotecan and two had received cetuximab alone. Of the 16, four patients experienced major objective (response rate = 25%; 95% CI = 4% to 46%), demonstrating that the hypothesis that a negative EGFR stain would preclude the possibility of response to cetuximab is false.⁴¹⁴ A similar lack of correlation of EGFR staining and activity with panitumumab has also more recently been reported.⁴¹⁵

Because current EGFR IHC techniques have no predictive value, these techniques have no role in current management of CRC. The exclusion of a patient from cetuximab-based or panitumumab-based therapy solely on the basis of EGFR IHC is not appropriate. Likewise, no patient, with CRC or otherwise, should be given an anti-EGFR treatment solely on the basis of a high EGFR IHC expression.

Bevacizumab Plus Anti–Epidermal Growth Factor Receptor Agents

Given the reported activity of both bevacizumab and cetuximab, investigators logically became interested in the idea of concurrent use of these agents. Both some limited preclinical data, as well as mechanistic understandings of potential interaction between anti-EGFR and anti-VEGF pathways, supported the concept. As will be discussed subsequently, this concept serves as yet another example of perfectly logical, well-thought out assumptions supported by preliminary clinical evidence that turned out to be incorrect when subjected to the appropriately rigorous test of an adequately powered clinical trial.

The first study to attempt to administer bevacizumab and cetuximab concurrently was a small randomized phase 2 study of bevacizumab added to cetuximab alone or to cetuximab plus irinotecan in patients with irinotecan-refractory CRC.⁴¹⁶ This was a feasibility trial to assess the safety of concurrent administration of these agents and to look for preliminary evidence of efficacy. The study concluded that coadministration of these two monoclonal antibodies together was feasible, and that the preliminary data were encouraging. It should be noted, however, that this was a small feasibility trial with 41 and 40 patients, respectively, reported in each arm. Furthermore, this study was conducted in patients who were naive to both cetuximab and bevacizumab. As most patients now receive bevacizumab with their first-line regimen, the results in the bevacizumab-naive population might not necessarily have a bearing on current practice today. A small follow-up trial in patients with prior progression on a front-line bevacizumab-containing regimen showed far less activity, with 3 of 33 patients (9%) achieving a partial response and a median time to tumor progression of 3.9 months.⁴¹⁷ These small trials were designed to serve as the safety pilots for large-scale front-line studies that combined bevacizumab plus cetuximab with front-line chemotherapy. Two such studies have now been reported, with alarming results, which highlights the dangers of jumping to conclusions prior to the availability of mature, definitive data.

The CAIRO-2 study randomized 755 patients with previously untreated metastatic CRC to Cape/Ox-bevacizumab with or without concurrent cetuximab (Table 57.19A).⁴¹⁸ Not only was there not a benefit to the addition of cetuximab, but the group receiving cetuximab actually had a worse median progression-free survival of 9.4 months, compared to 10.7 months in the Cape/Ox-bevacizumab-alone arm ($p = 0.01$). Response rates were identical

TABLE 57.19A

Capecitabine, Oxaliplatin, and Bevacizumab with or without Cetuximab in Metastatic Colorectal Cancer

Overall	Median Progression-Free Survival	Median Response	Objective Survival Rates
COB (<i>n</i> = 332)	20.3 mo	10.7 mo	50%
COB plus cetux (<i>n</i> = 317)	19.4 mo	9.4 mo	52.7%
<i>P</i> value	0.16	0.01	0.49

COB, capecitabine, oxaliplatin, bevacizumab; cetux, cetuximab.

(44%) in the two arms. Furthermore, quality-of-life scores were lower in the cetuximab-containing arm. Overall survival was not statistically significantly different between the two groups. Even for the wild-type KRAS patients, there was no benefit in progression-free survival with the addition of cetuximab. As might now be anticipated (Table 57.19B), within the cetuximab-containing arm, patients whose tumors had mutated KRAS had statistically significantly decreased progression-free survival compared to those with wild-type KRAS tumors (8.1 months versus 10.5 months; $p = 0.04$). However, for the patients with KRAS mutations, those who received cetuximab also had a worse outcome than those on the noncetuximab-containing control arm (progression-free survival 8.1 months versus 12.5 months, $p = 0.003$; overall survival 17.2 months versus 24.9 months, $p = 0.03$).

Another study that investigated the use of combined bevacizumab plus anti-EGFR monoclonal antibody was the Panitumumab in Advanced Colon Cancer Evaluation (PACCE) trial.⁴¹⁹ This trial used FOLFOX-bevacizumab (823 patients) or FOLFIRI-bevacizumab (230 patients) and randomized them with or without concurrent panitumumab. Again, the result of adding the anti-EGFR to chemotherapy plus bevacizumab was not only not beneficial, but was actually detrimental. The median progression-free survival for the overall study was 10.0 months versus 11.4 months for the panitumumab-containing versus chemotherapy-bevacizumab-alone arm. The median overall survival was decreased by 5.1 months, from 24.5 months in the control arm to 19.4 months in the panitumumab arm. Toxicity, including not only skin rash but also diarrhea, infections, and pulmonary embolisms, was more frequent in the panitumumab-containing arm, and worse outcomes were seen in the panitumumab-containing arm regardless of KRAS mutation status.

Clearly, the concurrent use of anti-EGFR monoclonal antibodies, bevacizumab, and cytotoxic chemotherapy, despite supportive encouraging preliminary data, is not an acceptable treatment strategy. The reasons for this unanticipated negative interaction remain unknown at this time.

Oral Epidermal Growth Factor Receptor, Vascular Endothelial Growth Factor, and Cyclooxygenase-2 Inhibitors

The limited experiences with the oral EGFR tyrosine kinase inhibitors gefitinib (ZD1839) and erlotinib (OSI-774) in CRC have been essentially negative, and at present there is no role for these agents in this disease.^{420,421} This is consistent with the findings that the activating mutation seen in lung cancer required for anti-EGFR tyrosine kinase activity does not appear to occur in CRC.

Oral VEGF tyrosine kinase inhibitors, with the exception of regorafenib noted previously, have been similarly disappointing. Sunitinib showed essentially no activity as a single agent in chemotherapy-refractory disease, and front-line trials of chemotherapy with or without sunitinib, as well as chemotherapy with or without sorafenib, have now been closed early by their respective data monitoring committees for futility.⁴²² Two large, randomized trials of FOLFOX with or without the investigational VEGF tyrosine kinase inhibitor PTK-787 have also been reported as negative trials.

Cyclooxygenase-2 Inhibitors. Cyclooxygenase-2 (COX-2) catalyzes the synthesis of prostaglandins in the inflammatory response process. COX-2 has been frequently shown to be upregulated in malignant and premalignant tissues. COX-2 expression has been correlated with increased invasiveness, resistance to apoptosis, and increased angiogenesis.⁴²³ The science behind COX-2 inhibition appeared so compelling that many clinicians had chosen to add drugs such as celecoxib or rofecoxib (now withdrawn from the market for safety reasons) in the absence of efficacy data with the assumption that “it couldn’t hurt.” Evidence that use of either NSAIDs or selective COX-2 inhibitors has a beneficial role in the treatment of CRC is lacking. The large randomized BICC-C trial showed no benefit whatsoever for the use of celecoxib in terms of either safety or efficacy.³³⁴ In the absence of any emerging data to the contrary, routine use of COX-2 inhibitors with chemotherapy is not recommended.

The role of aspirin as an adjuvant agent is also of particular interest, especially after a recent case-control study suggested that

TABLE 57.19B

Impact of KRAS Mutation Status on Addition of Cetuximab to Capecitabine, Oxaliplatin, and Bevacizumab

	Overall Survival COB + COB cetux	Progression-Free Survival COB + COB cetux
KRAS wild-type	22.4 mo 21.8 mo ($p = 0.64$)	10.6 mo 10.5 mo ($p = 0.30$)
KRAS mutated	24.9 mo 17.2 mo ($p = 0.03$)	12.5 mo 8.1 mo ($p = 0.003$)

COB, capecitabine, oxaliplatin-bevacizumab; cetux, cetuximab.

From Tol J, Koopman M, Cats A, et al. Chemotherapy, bevacizumab, and cetuximab in metastatic colorectal cancer. *N Engl J Med* 2009;360:563–572.

initiation of this medication after diagnosis reduced overall CRC specific mortality (HR = 0.53; 95% CI = 0.33 to 0.86).⁴²⁴ The ASCOLT study is the first randomized, placebo-controlled trial designed to investigate this question in patients with stage III-IV and high-risk stage II disease. End points will include DFS and overall survival with anticipated follow-up of 5 years.⁴²⁵

In the meantime, a large observational study of 4,481 patients lends further support to the potential therapeutic benefits of aspirin in CRC. The authors report a 23% decrease in disease-specific mortality for patients who took aspirin for any length of time after diagnosis compared to nonaspirin users as well as a 30% lower disease-specific mortality for those who took aspirin for 9 months after diagnosis. A survival benefit was also found for prediagnosis users, although this was less pronounced at 12%.⁴²⁶

Other Novel Agents

The number of agents that are undergoing early evaluation in CRC is too large to allow a complete discussion of these in this chapter. Many are variations on the currently available agents and are unlikely to substantially move the field if successful in gaining approval. At present, no new agent with a unique mechanism of action has been identified as having meaningful activity in CRC. Furthermore, all of these at this point are of research interest only and do not have a role in standard treatment of CRC at this time.

MOLECULAR PREDICTIVE MARKERS

With the availability now of a number of active agents, the ability to prospectively select a particular drug or drug combination

that would have an increased likelihood of efficacy or a decreased likelihood of toxicity would be clinically useful. Such means of rational selection do not yet exist.

One avenue of investigation has been the elucidation of markers of resistance to 5-FU based on knowledge of its metabolic pathways. Studies have indicated that high levels of either TS, DPD,⁴²⁷ or thymidine phosphorylase, as measured in a tumor specimen by reverse transcription-polymerase chain reaction, predict for failure to respond to an infusional 5-FU regimen.^{166,428,429} These observations are intriguing but are insufficient to exclude the use of 5-FU in a particular patient, and they need to be validated in large-scale prospective trials before being applied to routine practice. There is, at this time, no role for the use of these markers in standard practice. Others have investigated genomic analysis as an indicator of response or toxicity.^{170,430} Although these approaches appear promising, they are not yet validated and should not be considered as part of standard care.

A recently reported mechanism of resistance thought to be independent of other mutations or MSI involves the tumor suppressor gene TFAP2E (transcription factor AP-2 epsilon) and its downstream target DKK4 (dickkopf homolog 4 protein). In an analysis of 220 patients with CRC, Ebert et al.⁴³¹ found that hypermethylation of TFAP2E led to decreased protein expression and was significantly associated with nonresponse to 5-FU-based chemotherapy, whereas hypomethylation yielded a six-fold higher likelihood of response. Moreover, TFAP2E hypermethylation in vitro led to overexpression of DKK4, which was in turn associated with increased chemoresistance to 5-FU but not irinotecan and oxaliplatin. The authors suggest that future studies focus on specific targeting of DKK4 to overcome this pathway of chemoresistance.⁴³¹

58 Genetic Testing in Colon Cancer (Polyposis Syndromes)

Kory W. Jasperson

INTRODUCTION

Hereditary colonic polyposis conditions account for less than 1% of all colorectal cancers (CRC). Accurate classification of these conditions is imperative, given their distinct cancer risks, management strategies, and consequent risk to relatives. However, overlapping features and atypical or attenuated presentations make diagnosis difficult in some cases. Determining the histologic types of colorectal polyps identified is especially useful in guiding diagnostic strategies. Adenomatous polyps are the predominant lesion in familial adenomatous polyposis (FAP), attenuated FAP (AFAP), and *MUTYH* (*MutY* human homolog)-associated polyposis (MAP), whereas hamartomatous polyps are the primary gastrointestinal lesion in Peutz-Jeghers syndrome (PJS), juvenile polyposis syndrome (JPS), and Cowden syndrome (CS). Extracolonic features, which are highlighted for each syndrome in Tables 58.1 to 58.3 are also important clues in the diagnostic workup. Genetic testing is now available for these conditions and, in most cases, allows for a precise diagnosis.

ADENOMATOUS POLYPOSIS

Familial Adenomatous Polyposis and Attenuated Familial Adenomatous Polyposis

Of all of the colonic polyposis conditions, FAP is both the most common and the best characterized. FAP is caused by germ-line mutations in the adenomatous polyposis coli (*APC*) gene and is estimated to occur in about 1 in 10,000 individuals. With the classic presentation of FAP, hundreds to thousands of adenomatous polyps occur by the age of 20 to 40 years.¹ The attenuated or less severe colonic phenotype associated with AFAP may mimic sporadic colon polyps and cancer, or other known syndromes, such as MAP. This creates diagnostic difficulties when evaluating an individual with moderate adenomatous polyposis. Other conditions linked to germ-line *APC* mutations include Gardner syndrome (with association of colonic polyposis and osteomas, epidermoid cysts, fibromas, and/or desmoid tumors) and Turcot syndrome (with association of colonic polyposis and medulloblastomas).² However, it is now believed that the features associated with Gardner syndrome and Turcot syndrome are the result of variable expressivity of *APC* mutations as opposed to being distinct clinical entities.

Colon Phenotype

Although adenomatous polyps associated with FAP have a similar malignancy rate as those that develop in the general population, the sheer number of polyps present in FAP results in nearly a 100% lifetime risk of CRC in untreated individuals. In FAP, colorectal polyps begin to develop on average around the age of 16 years.¹ The mean age at CRC onset is 39 years, with 7% developing CRC by 21 years and 95% before the age of 50 years.³

In AFAP, the lifetime risk of CRC is approximately 70% with an average age at onset in the 50s.⁴ The colonic phenotype of AFAP is quite variable, even within the same family. Colonoscopies in 120 mutation-positive individuals within the same family revealed that 37% had less than 10 adenomatous colon polyps (average age, 36 years; range, 16 to 67 years), 28% had 10 to 50 polyps (average age, 39 years; range, 21 to 76 years), and 35% had greater than 50 polyps (average age, 48 years; range, 27 to 49 years).⁴ In addition, the total number of polyps per individual ranged from zero to 470.⁴

Extracolonic Features

The most common extracolonic finding in individuals with FAP and AFAP is upper gastrointestinal tract polyps. Although the colonic phenotype in AFAP is less severe than in FAP, the upper gastrointestinal phenotype is comparable. Adenomatous polyps of the duodenum (20% to 100%) and the periampullary region (at least 50%) are common.^{5,6} The relative risk of duodenal or periampullary carcinoma in FAP is estimated to be 100 to 330 times greater than the general population, although the absolute risk is only around 5%.⁵ The majority of FAP- and AFAP-associated small-bowel carcinomas arise in the duodenum.

Fundic gland polyps are found in most cases of FAP/AFAP and often number in the hundreds.⁷ Unlike polyps in the colon or small bowel, fundic gland polyps are a type of hamartoma. They are typically small (1 to 5 mm), sessile, and usually asymptomatic and are located in the fundus and body of the stomach.⁷ Adenomatous polyps of the stomach are occasionally found in FAP and AFAP.⁸ Gastric cancers arising from fundic gland polyps have been reported in FAP, although most are believed to arise from adenomatous polyps.⁸ Individuals with FAP have an 800-fold increased risk for desmoid tumors (aggressive fibromatoses), with a lifetime risk of 10% to 30%.⁹⁻¹¹ Risk factors for desmoid tumors in FAP include a family history of desmoid tumors, *APC* mutations 3' to codon 1,399 (genotype-phenotype correlation), female sex, and previous abdominal surgery.¹⁰ Although desmoid tumors do not metastasize, they can be locally invasive, aggressive, and difficult to treat, resulting in significant morbidity and the second leading cause of mortality in FAP.¹²

The phenotypic spectrum of germ-line *APC* mutations also includes other benign findings such as osteomas, epidermoid cysts, fibromas, dental abnormalities, and congenital hypertrophy of the retinal pigment epithelium (CHRPE). In addition, there are increased risks for other cancers, including those of the pancreas, thyroid, bile duct, brain (typically medulloblastoma), and liver (specifically hepatoblastoma).⁶

Management

Without treatment, CRC is inevitable in FAP. However, with early screening and polypectomies, in addition to prophylactic colectomies after polyps become too difficult to manage endoscopically, most CRCs can be prevented in AFAP and FAP. In FAP, annual

TABLE 58.1

Characteristic Features and Recommendations: Adenomatous Polyposis Conditions

Lifetime Cancer Risks	Management Recommendations	Nonmalignant Features
FAP (APC)		
Colorectum (100%)	Annual colonoscopy/sigmoidoscopy by 10–12 y until colectomy	100–1,000s of colorectal adenomas
Duodenum (5%)	Upper endoscopy every 1–4 y by 25–30 y	Fundic gland polyposis
Stomach (\leq 1%)		Duodenal polyposis
Thyroid (1%–2%)	Annual physical examination	CHRPE, epidermoid cysts, osteomas
Pancreas (1%–2%)		Dental abnormalities
Hepatoblastoma (1%–2%)		Desmoid tumors
Medulloblastoma (<1%)		
AFAP (APC)		
Colorectum (70%)	Colonoscopy every 1–2 y by 18–20 y	10–100 colonic adenomas (range, 0–100s)
Duodenum (5%)	Upper endoscopy every 1–4 y by 25–30 y	Fundic gland polyposis
Stomach (\leq 1%)		Duodenal polyposis
Thyroid (1%–2%)	Annual physical examination	Other nonmalignant features are uncommon
Pancreas (1%–2%)		
MAP (biallelic MUTYH)		
Colorectum (80%)	Colonoscopy every 3 y by 25–30 y	10–100 colonic adenomas (range, 0–100s)
Duodenum (4%)	Upper endoscopy every 3–5 y by 30–35 y	Multiple hyperplastic and sessile serrated polyps possible
		Duodenal adenomatous polyposis

Data derived from National Comprehensive Cancer Network. NCCN Guidelines and Clinical Resources Web site. Colorectal Cancer Screening, Version 1.2012. 2012. <http://www.nccn.org>. Accessed April 3, 2012.

colonoscopies or flexible sigmoidoscopies are recommended starting around the age of 10 years.¹³ In AFAP, screening begins in the late teenage years, and colonoscopies, rather than sigmoidoscopies, are necessary because of proximally located polyps.¹³ Colectomies can sometimes be avoided in AFAP, which is not the case for individuals with FAP. After polyps become too numerous (usually >20 to 30 polyps) to manage endoscopically or when adenomas with advanced histology are identified, a prophylactic colectomy is advised.¹³ A proctocolectomy with an ileal pouch anal anastomosis is the standard surgery in FAP, whereas a total colectomy with ileorectal anastomosis is often the preferred approach with AFAP or in FAP cases with limited rectal involvement.^{13,14} Continued screening of the remaining rectum or ileal pouch is still necessary.¹³

Recently, it has been shown that duodenal cancer detected through surveillance improves survival compared with individuals presenting because of symptoms.¹⁵ The National Comprehensive Cancer Network (NCCN) currently recommends the consideration of an esophagogastroduodenoscopy (EGD) with a side-viewing examination beginning around the age of 25 years for duodenal cancer surveillance.¹³ The extent of duodenal polyps, as defined by the Spigelman staging criteria, is used to determine the EGD follow-up interval.¹³ Additional considerations for the management in individuals with germ-line APC mutations are outlined and updated annually by the NCCN (www.nccn.org).

Genetic Testing and Counseling

A clinical diagnosis of FAP is considered when at least 100 colorectal adenomatous polyps are detected by the 2nd or 3rd decade of life.⁶ Genetic testing of APC is still recommended to clarify extracolonic cancer risks and to help determine FAP status in relatives.

Genetic testing has also been shown to be cost-effective,¹⁶ although it is unlikely to change colon management for cases with extensive adenomatous polyposis.

Given the phenotypic variability, a consensus as to what constitutes a diagnosis of AFAP has not been reached. The NCCN currently recommends that individuals with greater than 10 cumulative colorectal adenomas be referred for genetic counseling and the consideration of genetic testing.¹³ The identification of an APC mutation in these less severe polyp cases confirms a diagnosis of AFAP. It is also noteworthy that individuals with 100 or more adenomatous polyps may have AFAP if polyp development occurs at a later age (typically after 40 years).

Differentiating among FAP, AFAP, and other colonic polyposis conditions is not always straightforward. Family history, which is consistent with an autosomal-dominant mode of inheritance, is suggestive of FAP/AFAP and increases the likelihood of finding an APC mutation.⁶ However, 10% to 30% of probands with germ-line APC mutations are de novo (new mutation) cases, and consequently, their parents are unaffected.^{6,17} In addition, it is not uncommon for individuals with AFAP to have less than 10 cumulative adenomatous polyps.⁴ In patients with fewer polyps, it is not clear whether genetic testing should be performed.¹³ However, it is important that these individuals be closely followed up, and if multiple adenomas continue to develop, genetic testing should be reconsidered.

Unlike what is found in some of the other conditions described in this review, hyperplastic or hamartomatous colon polyps are not known to be associated with FAP/AFAP. Therefore, if multiple hyperplastic or hamartomatous colon polyps are found in an individual, a genetic testing of APC is unlikely to be informative. Other features associated with APC mutations that may assist with making a diagnosis of AFAP or FAP include fundic gland polyposis, duodenal adenomatous polyps, osteomas, CHRPE, desmoid tumors, and hepatoblastoma.⁶

MUTYH-Associated Polyposis

As the name implies, MAP is a colonic polyposis condition caused by germ-line mutations in the *MUTYH* gene. Contrary to the other conditions described in this review, MAP is inherited in an autosomal-recessive pattern. In 2002, Al-Tassan et al.¹⁸ were the first to describe a family with biallelic (homozygous or compound heterozygous) mutations in *MUTYH*, which is part of the base excision repair system. In this family, three siblings had CRC and/or multiple colorectal adenomas, but no detectable mutations in *APC*.¹⁸ All three of the affected siblings were found to have compound heterozygous mutations in *MUTYH*, whereas the other four unaffected siblings did not.¹⁸

It is now widely accepted that MAP is associated with a significant increased risk for multiple colorectal adenomas and cancer. Whether monoallelic *MUTYH* carriers have a modest increase in risk of CRC is debatable.¹⁹ Monoallelic mutations in *MUTYH* are found in 1% to 2% of the general population, whereas biallelic mutations account for less than 1% of all CRCs.²⁰

Colonic Phenotype

There are a number of similarities between the colonic phenotype of MAP and AFAP, including the average number, proximal distribution, and young age at onset of adenomas and cancers.^{4,19} *MUTYH*-associated polyposis is associated with a 28-fold increased risk of CRC, with a penetrance of 19% by the age of 50 years, 43% by 60 years, and 80% by 70 years.^{19,21} Although the risk of CRC has been reported to be as high as 100%,²² the actual penetrance is likely to be incomplete and similar to that of AFAP. The total number of polyps in MAP is also highly variable, with some individuals developing CRC without polyps, whereas others have more than 500 colorectal polyps.²³ Typically, affected individuals have between 10 and 100 polyps.²³

Adenomas are the predominant polyp type seen not only in AFAP and FAP, but also in MAP. Unlike individuals with germ-line *APC* mutations, serrated polyps are common in MAP. Serrated polyps include hyperplastic polyps, sessile serrated polyps (also referred to as sessile serrated adenomas), and traditional serrated adenomas.²⁴ Boparai et al.²⁵ evaluated 17 individuals with MAP and found that almost one-half (47%) had hyperplastic and/or sessile serrated polyps. In addition, three met the criteria for hyperplastic polyposis, now known as serrated polyposis. The World Health Organization diagnostic criteria for serrated polyposis include an individual with any of the following: (1) at least five serrated polyps proximal to the sigmoid colon with at least two larger than 10 mm; (2) greater than 20 serrated polyps of any size, but distributed through the colon; and (3) any number of serrated polyps proximal to the sigmoid colon in an individual with a first-degree relative with serrated polyposis.²⁴ Interestingly, Chow et al.²⁶ also identified biallelic *MUTYH* mutations in 1 (~3%) of 38 cases meeting hyperplastic polyposis/serrated polyposis criteria. Another family involving three brothers with biallelic *MUTYH* mutations has recently been reported, further highlighting this variability in phenotype. Their history included one with CRC at the age of 48 years but had no additional polyps, another was 38 years old and reportedly met criteria for serrated polyposis but had only two confirmed adenomas, and the other brother was 46 years old and had four hyperplastic polyps removed.²⁷ Currently, the etiology of serrated polyposis is largely unknown; however, there is growing evidence that the base excision repair pathway may be involved in a minority of these cases.

Boparai et al.²⁵ also compared the frequency of *KRAS* mutations and G:C to T:A transversions in hyperplastic or sessile serrated polyps in individuals with MAP to controls. In MAP, 51 (70%) of 73 serrated polyps had *KRAS* mutations, and 48 (94%) of these 51 had G:C to T:A transversions, whereas in the control group, only 7 (17%) of 41 serrated polyps had *KRAS* mutations, and 2 (29%) of 7 had G:C to T:A transversions.²⁵ These findings support an association between MAP and serrated polyps.

Extracolonic Features

A number of extracolonic findings have been reported in individuals with MAP.²³ However, it is still unclear whether most of these manifestations are chance occurrences or due to an underlying defective *MUTYH*. In a study of 276 individuals with MAP, only two developed duodenal cancer.²² However, compared with the general population, the risk of duodenal cancer was significantly elevated, with a standard incidence ratio of 129 and an estimated lifetime risk of 4%.²² Although the lifetime risk of duodenal cancer is similar between MAP and FAP/AFAP (4% and 5%), gastric and duodenal polyps are far less common in MAP. Of 150 individuals with MAP who underwent an EGD, 11% had gastric polyps, whereas 17% had duodenal polyps.²²

Extraintestinal malignancies have also been reported in MAP,²² although the data supporting an association are conflicting.^{28,29} Desmoid tumors, thyroid and brain cancer, CHRPE, osteomas, and epidermoid cysts are rarely seen in MAP.²³

Genetic Counseling and Testing

Since the first reported family with biallelic *MUTYH* mutations was described in 2002, more than 500 individuals with MAP have been confirmed.²³ As was the case with this first MAP family, genetic testing strategies to evaluate for *MUTYH* are typically targeted toward individuals with multiple colorectal adenomas. However, there are many other factors that can influence genetic testing approaches for *MUTYH* and *APC* mutations. Family history; age at polyp onset; types, location, and total number of polyps; CRC history (including age at onset and location); ethnicity; and extracolonic features are just some of the factors that influence genetic testing strategies and detection rates. The purpose of this review was not to present every scenario and strategy for *MUTYH* and *APC* genetic testing, but instead to outline some key concepts and considerations when multiple adenomas are detected.

Given the inheritance pattern of MAP, it is uncommon for more than one generation to be affected; however, a family history of CRC in more than one generation does not exclude MAP. Consanguinity (sharing a common ancestor) is seen in some MAP families and is an important element to evaluate for when taking a history. Siblings of affected individuals have a one in four chance (25%) of having MAP, whereas parents and children are obligate carriers. Therefore, when there is clear evidence of recessive inheritance in a family (more than one sibling affected in a family, but no one else), genetic testing should start with *MUTYH*. *APC* should still be evaluated in these families if no *MUTYH* mutations are identified, because germ-line mosaicism can result in more than one affected sibling with FAP and unaffected parents.³⁰ To clarify risk to offspring, spouses of individuals with MAP should also be offered *MUTYH* genetic testing. This strategy has been shown to be cost-effective.³¹

Generally, germ-line *APC* mutations are more common than biallelic *MUTYH* mutations; therefore, unless there is clear evidence for recessive inheritance in a family, *APC* genetic testing typically precedes *MUTYH* analysis. There are two common mutations in *MUTYH* that are found in the majority of affected individuals: Y179C and G396D (previously known as Y165C and G382D). These hotspot mutations were found in the original MAP family.¹⁸ According to Nielsen et al.,²³ a review up to 2009 revealed more than 100 distinct *MUTYH* mutations. In individuals with Northern European ancestry and MAP, at least one of the two hotspot mutations are found in 90% of cases.^{23,32} Testing specifically for the hotspot mutations, followed by full *MUTYH* sequencing only if one of these mutations is found, is often performed. In other populations, the scope of *MUTYH* mutations is less well understood, and therefore, full gene sequencing of *MUTYH* is often performed in individuals of non-Northern European ancestry. Similar to *APC*, genetic testing of *MUTYH* is considered when greater than 10 adenomas are documented.^{13,23} The detection rates of biallelic *MUTYH* mutations

in individuals with 10 to 100 and 100 to 1,000 polyps are 28% and 14%, respectively.²³ Given the growing evidence that hyperplastic and sessile serrated polyps are associated with MAP, these polyps should also be included in the total polyp count when considering when to test someone for *MUTYH* mutations. Individuals with FAP/AFAP are not known to develop numerous serrated polyps; therefore, genetic testing of *APC* in someone with multiple serrated polyps is unlikely to be informative. The NCCN guidelines do not currently recommend genetic testing of *MUTYH* in individuals with multiple serrated polyps and no adenomas.¹³

It is not unusual for individuals with MAP or AFAP to present with early-onset CRC and few to no polyps.^{4,33} However, a consensus as to whether genetic testing of *APC* or *MUTYH* should be performed in these cases has not yet been reached.^{13,23}

Management

Colonoscopy screening starting at around the age of 25 years is recommended for individuals with MAP.¹³ The frequency of screening depends on polyp burden. As is the case with AFAP and FAP, colectomy is advised when polyps become endoscopically uncontrollable. EGDs should be considered in the 30s and, if duodenal adenomas are found, managed the same as in AFAP and FAP.¹³ Currently, the evidence does not support increased CRC screening in monoallelic *MUTYH* carriers.

HAMARTOMATOUS POLYPOSIS

Peutz–Jeghers Syndrome

PJS is an autosomal dominant condition caused by mutations in the *STK11/LKB1* gene. It is estimated to occur in 1 in 50,000 to 200,000 births.³⁴ The two most characteristic manifestations of PJS are the distinct gastrointestinal-type hamartomas, called Peutz–Jeghers polyps, and the mucocutaneous melanin pigmentation. Both of these features are included in the diagnostic criteria for PJS (Table 58.2). Although it is not 100% penetrant and can fade with time, mucocutaneous hyperpigmentation in PJS typically presents in childhood. By the age of 20 years, 50% of individuals present with small-bowel obstruction, intussusception, and/or bleeding due to small-bowel polyps.³⁵ The polyps in PJS can also number in the hundreds and are most often found in the small intestine, followed by the colon and the stomach.³⁴

The cancer risks associated with PJS are more significant after the age of 30 years, although earlier-onset malignancies do occur. In the largest study to date of 419 individuals with PJS, the risk of developing any cancer was 2% by the age of 20 years, 5% by 30 years, 17% by 40 years, 31% by 50 years, 60% by 60 years, and 85% by 70 years.³⁶ Gastrointestinal tract cancers had the highest cumulative risk. The specific cancer risks associated with PJS are outlined in Table 58.3.

Juvenile Polyposis Syndrome

JPS is an autosomal-dominant condition caused by germ-line mutations in *SMAD4* or *BMPRIA* genes, with an incidence of 0.6 to 1 in 100,000 and a de novo rate of 25% to 50%.^{37,38} Juvenile polyps are the hallmark lesion in JPS.³⁸ They are most commonly found in the colorectum and can number in the hundreds, although the carpeting of polyps is not usually seen in JPS like it is in FAP.³⁸ Of note, solitary juvenile polyps can occur in children without JPS (see Table 58.2). Hematochezia is the most common presenting symptom and, similar to PJS, intussusception and obstruction are common. The highest risk of cancer (see Table 58.3) in JPS is CRC. Gastric cancers typically occur only in the setting of gastric polyposis, which is more commonly present in individuals with

TABLE 58.2

Testing and Diagnostic Criteria for Peutz–Jeghers Syndrome, Juvenile Polyposis Syndrome, and Cowden Syndrome

PJS

A clinical diagnosis of PJS is considered when any of the following are met:

- (1) ≥ 3 histologically confirmed Peutz–Jeghers polyps
- (2) Any number of Peutz–Jeghers polyps and a family history of PJS
- (3) Characteristic, prominent, mucocutaneous pigmentation and a family history of PJS
- (4) ≥ 1 Peutz–Jeghers polyp and characteristic, prominent, mucocutaneous pigmentation

JPS

A clinical diagnosis of JPS is considered when any of the following are met:

- (1) 3–5 juvenile polyps of the colorectum
- (2) Juvenile polyps throughout the gastrointestinal tract
- (3) ≥ 1 juvenile polyp in an individual with a family history of JPS

CS^a

Genetic testing for CS is considered in individuals meeting any of the following criteria:

- (1) Adult onset Lhermitte–Duclos disease
- (2) Autism spectrum disorder and macrocephaly
- (3) ≥ 2 major criteria (one must be macrocephaly)
- (4) ≥ 3 major criteria without macrocephaly
- (5) Bannayan–Riley–Ruvalcaba syndrome
- (6) One major and ≥ 3 minor criteria
- (7) ≥ 2 biopsy-proven trichilemmomas
- (8) ≥ 4 minor criteria

Major Criteria	Minor Criteria
Multiple gastrointestinal (GI) hamartomas/ganglioneuromas	A single GI hamartoma/ganglioneuroma
Nonmedullary thyroid cancer	Thyroid adenoma or multinodular goiter
Breast cancer	Fibrocystic disease of the breast
Endometrial cancer	Mental retardation (i.e., IQ ≤ 75)
Mucocutaneous lesions	Autism spectrum disorder
One biopsy proven trichilemmoma	Fibromas
Multiple palmoplantar keratoses	Renal cell carcinoma
Multiple cutaneous facial papules	Uterine fibroids
Macular pigmentation of glans penis	Lipomas
Multifocal/extensive oral mucosal papillomatosis	
Macrocephaly (megalcephaly) (at least 97th percentile)	

IQ, intelligence quotient.

TABLE 58.3

Characteristic Features and Recommendations: Peutz–Jeghers Syndrome and Juvenile Polyposis Syndrome

Lifetime Cancer Risks	Management Recommendations	Nonmalignant Features
PJS (<i>STK11</i>)		
Breast (54%)	Annual mammogram and breast magnetic resonance imaging by age 25 y	Mucocutaneous pigmentation
Colon (39%)	Colonoscopy every 2–3 y by age 25 y	
Pancreas (11%–36%)	CA19-9 and magnetic resonance cholangiopancreatography and/or endoscopic ultrasound every 1–2 y	Peutz–Jeghers polyps
Stomach (29%)	Upper endoscopy by 25–30 y; consider small-bowel visualization (computed tomography [CT] enterography, small-bowel enteroclysis) by 8–10 y	
Small bowel (13%)		
Ovary ^a (21%)	Annual pelvic examination and Pap smear	
Uterine/cervix ^b (11%)		
Lung (15%)	No specific recommendations	
Testicle ^c (<1%)	Annual testicular examination	
JPS (<i>SMAD4</i> and <i>BMPRI1A</i>)		
Colon (40%–50%)	Colonoscopy by age 15 y repeating annually if polyps are present and every 2–3 y if no polyps	Juvenile polyps Features of hereditary hemorrhagic telangiectasia
Stomach (21% if gastric polyps are present)	Upper endoscopy by age 15 y repeating annually if polyps are present and every 2–3 y if no polyps	Congenital defects

^a Sex cord tumor with annular tubules.

^b Adenoma malignum.

^c Sertoli cell tumor.

mutations in *SMAD4* than in *BMPRI1A*.³⁷ JPS occurring in infancy (also known as juvenile polyposis of infancy) is often fatal, but rare. Hereditary hemorrhagic telangiectasia symptoms, such as arteriovenous malformations, telangiectasia, and epistaxis, occur in some individuals with mutations in *SMAD4*, but not *BMPRI1A*.³⁷

Cowden Syndrome

CS, which is part of the phosphatase and tensin homolog (*PTEN*) hamartoma tumor syndrome, occurs in about 1 in 200,000 to 1 in 250,000 individuals and is caused by germ-line mutations in the *PTEN* gene.³⁹ It is a multisystem disorder associated with characteristic mucocutaneous features, macrocephaly, and a variety of cancers and gastrointestinal manifestations.³⁹ Although other malignancies may be seen in CS, the primary cancers associated with CS include breast (25% to 50%), nonmedullary thyroid (3% to 10%), and endometrial (5% to 10%).³⁹ A recent study estimated that the lifetime risk for these cancers in *PTEN* mutation carriers was 85%, 35%, and 28%, respectively.⁴⁰ However, these risks are likely overestimates, because Tan et al.⁴⁰ failed to accurately account for ascertainment bias in their study.

Gastrointestinal polyps are one of the most common features in CS.⁴¹ Polyps develop throughout the gastrointestinal tract, from the esophagus to the rectum, and numerous polyps or diffuse polyposis can be seen.⁴¹ Multiple, white flat plaques in the esophagus, called glycogenic acanthosis, also occur in the setting of CS. In a large study of 127 individuals with *PTEN* mutations, 39 underwent at least 1 EGD, and 8 (~23%) had glycogenic acanthosis, 26 (~67%) had duodenal and/or gastric polyps, and only 2 (5%) had fundic gland polyps.⁴¹ Of the 67 individuals who underwent

at least 1 colonoscopy, 62 (~93%) had colonic polyps, and 16 met criteria for hyperplastic polyposis.⁴¹ Although hamartomas predominate, a variety of other colon polyps also develop, including adenomatous, hyperplastic, sessile serrated, ganglioneuromatous, inflammatory, lymphoid, and lipomatous. Of all of the mutation carriers in this large study, nine (7%) were diagnosed with CRC.⁴¹

Peutz–Jeghers Syndrome, Juvenile Polyposis Syndrome, and Cowden Syndrome: Genetic Counseling and Testing

Hamartomatous polyps consist of an overgrowth of cells native to the tissue in which they occur. They are rare, account for a minority of all colon polyps, and can be a red flag for an underlying cancer predisposition syndrome. When hamartomatous polyps are found in an individual, the differential diagnosis depends, in part, on the histologic type, total number, and age at onset of the polyps. Hamartomas can often be misdiagnosed as other polyp types, and therefore, review by a gastrointestinal pathologist should be considered.⁴² When hamartomatous colonic polyps are identified, EGD and a thorough physical examination may identify extracolonic manifestations leading to a precise diagnosis. A detailed family history is also imperative. Diagnostic criteria for JPS and PJS are summarized in Table 58.2. Guidelines for genetic testing of CS, which are quite extensive and include a number of extraintestinal features, are also included in Table 58.2. Given the complexity of genetic testing for CS, the NCCN updates their guidelines annually.¹³ Management considerations are reviewed for PJS and JPS in Table 58.3 and are also updated annually by the NCCN.¹³

CONCLUSIONS

There are numerous presentations that may warrant genetic testing for hereditary colonic polyposis conditions. Simplified guidelines for referral for genetic counseling include individuals with any of the following: (1) greater than 10 colonic adenomas, (2) three or more hamartomatous polyps, or (3) at least one Peutz–Jeghers polyp. Other manifestations in these individuals may help target

genetic testing to a specific condition. Once the genetic cause has been identified in an affected individual, predictive testing in at-risk relatives is critical. Family members who test negative can be spared the increased surveillance and risk-reducing procedures that are warranted for family members who test positive. It is important that health-care providers involved in the care of patients with hereditary colonic polyposis conditions stay updated with management guidelines because recommendations are constantly evolving.

59 Genetic Testing in Colon Cancer (Nonpolyposis Syndromes)

Leigha Senter-Jamieson

INTRODUCTION

Approximately 5% to 10% of colorectal cancers (CRC) are hereditary and are often categorized by the presence or absence of polyposis as a predominant feature. Lynch syndrome (LS), also sometimes referred to as hereditary nonpolyposis CRC, is the most common form of hereditary CRC, accounting for approximately 2.2%¹ of population-based CRCs diagnosed in the United States. LS also accounts for 2.3%² of all newly diagnosed endometrial cancers (EC), and individuals with LS also have an increased risk of developing other cancers, including cancers of the ovary, stomach, small bowel, urothelium, and biliary tract.³ Given these increased cancer risks, cancer screening recommendations for individuals with LS differ significantly from general population screening recommendations with a goal of reducing the cancer risk and burden to the extent possible.

Mutations in one of four mismatch repair genes (*MLH1*, *MSH2*, *MSH6*, and *PMS2*) cause LS, and clinical genetic testing is available for all of them. Unlike most other hereditary cancer syndromes, however, clinical testing for LS typically begins with microsatellite instability (MSI) testing and/or immunohistochemical (IHC) staining of tumor tissue before germ-line genetic testing. This difference in testing approach, although not always possible, allows for targeted genetic analysis and, in most cases, reduced cost. Here, we review key considerations in genetic counseling for LS.

Cancer Risks

CRCs and ECs are the two most common LS-associated malignancies, and there have been several calculations of lifetime cancer risks reported in the literature. Differences in ascertainment and testing approaches have led not only to a wealth of data, but also to a wide range of risk estimates for consideration by clinicians and patients. Consistently, studies have found that the lifetime CRC risk for men with LS is higher than the risk for women with LS. The lifetime CRC risk for males is 27% to 92%, whereas the risk for females is 22% to 68%.^{4,5} The most recent large study of carriers of *MLH1*, *MSH2*, and *MSH6* mutations estimated lifetime CRC risks for males and females to be 38% and 31%, respectively.⁶ The average age at CRC diagnosis tends to be younger in LS (estimated 45 to 59 years) than that in the general population.^{6,7} The lifetime risk of EC for women with LS based on recent data is estimated to be 33% to 39%.^{6,8} Individuals with LS who have already been diagnosed with CRC also have an increased risk (10-year risk of 16%) of developing a second primary CRC.⁹

In addition to sex differences in LS-associated cancer risks, there appear to be some differences in gene-specific-associated cancer risks, as well. *MLH1* and *MSH2* seem to be associated with a higher overall cancer risk than risks associated with *MSH6* or *PMS2*.^{10,11} A variable expression of phenotype both within and among families with LS is common. Therefore, as a general rule, management of families with LS (discussed later) should always take into account the family history.

Malignancies of the ovary, stomach, small bowel, urothelium, and biliary tract are also seen with greater frequency in individuals with LS when compared with the general population. Although cumulative risk estimates of these less common tumor types have been published, they are usually based on fewer cases than studies focused on CRCs and ECs, and have typically shown a lifetime cancer risk of less than 10%.³ There have also been reports of LS-associated pancreatic and breast cancers, but the data have been inconsistent. A recent prospective study showed an increased risk of developing both tumor types when comparing carriers of *MMR* gene mutations to their unaffected relatives.¹² Additional data are necessary, however, to determine whether screening recommendations should change based on these reported risks. Some individuals with LS also have a predisposition to developing sebaceous lesions and keratoacanthomas of the skin. When an individual has one of these lesions in addition to a visceral organ malignancy, they have a variant of LS called Muir-Torre syndrome.¹³ Some recent studies suggest that these skin lesions are more common in LS than originally thought and that sebaceous tumors of the skin should be considered part of the typical LS spectrum.¹⁴ Another variant of LS characterized by the presence of glioblastomas is called Turcot syndrome. Turcot syndrome is more commonly caused by mutations in the *APC* gene but has been described in individuals with mismatch repair (*MMR*) deficiency, as well.¹⁵

CLINICAL CLASSIFICATION: AMSTERDAM CRITERIA AND BETHESDA GUIDELINES

In 1991, the International Collaborative Group on Hereditary Non-Polyposis CRC wrote the Amsterdam I criteria¹⁶ and revised them in 1999 (Amsterdam II criteria)¹⁷ to clinically classify families as having LS (Table 59.1). The Amsterdam criteria rely heavily on extensive family history and do not take into account the full spectrum of possible LS-associated tumors. The less stringent Bethesda guidelines (written in 1997 and revised in 2004)^{18,19} (Table 59.2) were written to include these less common LS-associated tumors as well as pathologic features that are common in LS-associated CRCs. Unlike the Amsterdam criteria, which were meant to diagnose LS based on familial criteria, the Bethesda guidelines were meant to determine who should have tumor screenings for LS and relied less on family history. It has been repeatedly shown, however, that these clinical classification systems do not reliably predict LS in all patient populations, particularly for those populations outside the cancer genetics clinics dedicated to high-risk patients.^{1,20}

TUMOR SCREENING

Microsatellites are pieces of DNA sequence where a single nucleotide or group of nucleotides is repeated multiple times. In general, the number of repeated nucleotide sequences should remain the same within a person's cells, but when this number of repeats

TABLE 59.1

Revised Amsterdam Criteria
≥3 relatives with colorectal, endometrial, small bowel, ureter, and/or renal pelvis cancer AND
One of these relatives is a first-degree relative ^a of the other two AND
≥2 successive generations are affected AND
At least one diagnosis is at the age of <50 y
Familial adenomatous polyposis is excluded
Tumors should be verified pathologically/histologically

differs in one or two alleles, MSI is present.²¹ In the case of LS, five microsatellite markers are used as the standard with which to measure MSI, and a tumor is considered to have a high level of MSI (MSI-H) if at least 40% of the markers are unstable.²² Nearly all LS-associated tumors display MSI, but the presence of MSI is not diagnostic of LS, given that approximately 10% to 15% of all CRCs, in general, also display MSI.^{23,24} MSI testing, however, can be used as a screening tool to help identify individuals for whom germ-line genetic testing for mutations in *MLH1*, *MSH2*, *MSH6*, and/or *PMS2* is indicated. A clinical diagnosis of LS can be made if a person has an MSI-H CRC and meets the Amsterdam II criteria (see Table 59.1).

Immunohistochemistry can be used to determine the presence or absence of MMR proteins in a tumor specimen and is another available screening test for LS. The absence of one or more MMR proteins in tumor tissue indicates dysfunction of the corresponding MMR gene, but additional analyses are required to determine if the dysfunction is germ line or somatic in nature. The benefit of performing IHC staining over MSI testing is that results from IHC staining can direct the approach to genetic testing. For instance, if a patient has CRC that demonstrates an absence of MSH2 and MSH6 proteins, testing for MSH2 with procession to testing for MSH6 if the MSH2 test results are negative is recommended. In

TABLE 59.2

Revised Bethesda Guidelines
Individuals with CRC should be tested for MSI if they have any of the following:
<ul style="list-style-type: none"> ■ CRC at the age of <50 y ■ Synchronous CRC (>1 CRC at the same time) or metachronous CRC (>1 CRC diagnosed at different times) or other LS-associated tumors^a ■ CRC with MSI-H histology (tumor-infiltrating lymphocytes, Crohnlike lymphocytic reaction, mucinous or signet-ring differentiation, medullary growth pattern) in a patient aged <60 y ■ CRC or LS-associated tumor^a diagnosed at the age of <50 y in FDR ■ CRC or LS-associated tumor^a in 2 FDR and/or SDR at any age

^a CRC, EC, stomach, small bowel, ovary, pancreas, ureter and renal pelvis, biliary tract, brain tumor, sebaceous adenomas, keratoacanthomas. FDR, first-degree relative (parent, sibling, child); SDR, second-degree relative (grandparent, aunt, uncle, grandchild).

Absence MSH2 and MSH6	<i>MSH2</i> germ-line testing <ul style="list-style-type: none"> ■ If negative, <i>TACSTD1</i> deletion testing ■ If negative, <i>MSH6</i> germline testing
Absence MSH6 only	<i>MSH6</i> germ-line testing <ul style="list-style-type: none"> ■ If negative, consider <i>MSH2</i> germ-line testing

^a If personal/family history highly suggestive of LS, it is appropriate to forgo *MLH1* methylation/*BRAF* testing.

^b Unless otherwise noted, "germ-line testing" here refers to sequencing/large rearrangement testing.

the context of this IHC result, it is generally not necessary to test for mutations in *MLH1* and/or *PMS2*. Strategies for genetic testing based on IHC results are included in Table 59.3.^{25,26} In comparing tumor screening strategies, using MSI and IHC staining together will identify the majority of LS cases. Because the sensitivity of either test is not 100%, using either test alone will leave 5% to 10% of LS cases undetected.^{27,28}

Epigenetic events unrelated to LS can cause a tumor to demonstrate MSI and an absence of MLH1 and PMS2 proteins upon IHC staining. These results can often be attributed to hypermethylation of the *MLH1* promoter and/or a somatic *BRAF* mutation (V600E). Several studies have shown that the V600E *BRAF* mutations are not associated with LS, and there have been very few exceptions.^{11,29} Both of these tests can be performed on CRC tissue to help determine whether germ-line genetic testing should be pursued, further streamlining the genetic testing process, but this should be interpreted in the context of clinical familial presentation because sensitivities and specificities for these tests are not 100%. It is important to note that it is possible but rare to have inherited *MLH1* promoter hypermethylation.³⁰

Similar approaches to screening EC with MSI and/or IHC staining are appropriate. However, because somatic *BRAF* mutations are uncommon in ECs, *BRAF* testing is not an appropriate test for ECs that are MSI-H and/or MLH1- and PMS2-protein deficient.³¹ There are less data to support MSI and/or IHC testing using other LS-associated tumor tissue, but many reports suggest that it is at least feasible in the absence of additional testing options.³²

In 2009, the Evaluation of Genomic Application in Practice and Prevention Working Group recommended that individuals with newly diagnosed CRCs be offered genetic testing for LS. Although the Evaluation of Genomic Application in Practice and Prevention Working Group did not specify the best approach for genetic testing, performing a tumor analysis with IHC staining allows for more targeted genetic testing and was considered to be an acceptable strategy.³³ In addition, multiple reports have shown that tumor screening with IHC staining is a cost-effective strategy for identifying LS in the CRC patient population.^{34,35} Ladabaum et al.³⁵ compared the differences among multiple testing strategies with regard to effect of life-years, cancer morbidity and mortality, and cost. They concluded that IHC staining with inclusion of *BRAF* gene testing if the MLH1 protein was absent was the preferred method of identifying LS among CRC patients.³⁵ The effectiveness of screening for LS in these reports has been dependent on the ability to test family members of the initially diagnosed

LS patient; therefore, genetic counseling and dissemination of information to relatives of probands are crucial for an effective diagnosis and the prevention of cancer.

GENETIC TESTING

In many situations, as mentioned previously, tumor screening tests are performed before germ-line genetic testing, but there are situations where this is not possible or desired (e.g., sufficient tumor tissue is unavailable, all individuals affected with cancer in a family are deceased). In the absence of IHC results to direct genetic testing, germ-line testing is typically done in a stepwise fashion beginning with *MLH1* and *MSH2*, which account for 32% and 38% of mutations, respectively.⁹ If no mutations are identified, testing for mutations in *MSH6* and *PMS2* is indicated. Mutations in these two genes are less common and account for 14% and 15% of LS, respectively.⁹ It is important for testing to include sequencing as well as an analysis of deletions and duplications because all mutation types have been reported in the *MMR* genes.

Recently, deletions in *TACSTD1* (also known as *EPCAM*), which is not an *MMR* gene, have been reported to cause an inactivation of *MSH2* and a lack of expression of the *MSH2* protein when IHC staining is performed. Therefore, testing for deletions in *TACSTD1* is indicated when the *MSH2* protein is absent on IHC staining, but no germ-line *MSH2* mutation has been identified.³⁶

GENETIC COUNSELING FOR LYNCH SYNDROME

Inherited in an autosomal dominant manner, first-degree relatives of individuals with LS have a 50% chance of having inherited the syndrome as well, making the communication of these risks to family members of patients with LS very important. Data have shown that compliance with the screening recommendations, as follows, is effective at reducing the risk of dying of cancer in individuals with LS, and this should be communicated to at-risk families. A large study of *MMR* mutation carriers in Finland found that despite the increased risks of CRCs and ECs, cancer mortality was not increased when individuals followed the intensive screening protocol and/or opted to have prophylactic surgery.³⁷

MANAGEMENT OF LYNCH SYNDROME

Individuals with LS require personalized management planning with the goal of reducing their cancer risks. Although many groups have put forth screening recommendations in the literature, the LS surveillance and screening recommendations from the National Comprehensive Cancer Network, which are updated annually, are commonly used in clinical practice. Based on these current recommendations, individuals with LS should have colonoscopy every 1 to 2 years beginning at the age of 20 to 25 years or 2 to 5 years earlier than the youngest CRC in the family if diagnosed before the age of 25 years. (A colonoscopy may be recommended to start at the age of 30 years in families with *MSH6* and *PMS2* mutations if the CRC age at onset in the family is not younger than the age of 30 years given the reduced penetrance with these genes.) Given that there is no clear evidence to support screening for endometrial and/or ovarian cancers, women with LS are recommended to consider a prophylactic hysterectomy and a bilateral salpingo-oophorectomy upon completion of childbearing. Some clinicians may find endometrial sampling, transvaginal ultrasound, and CA-125 serum screening to be helpful; however, these tools should be used at their discretion. To screen for gastric and small-bowel cancers, individuals with LS should consider an esophagogastroduodenoscopy with an extended duodenoscopy and a capsule endoscopy every 2 to 3 years beginning at the age of 30 to 35 years. An annual urinalysis beginning at the age of 25 to 30 years can be used to screen for urothelial cancers, and an annual physical examination to assess for symptoms of central nervous system tumors is reasonable.³⁸

A 2011 study by Burn et al.³⁹ showed through a randomized trial with postintervention double-blind follow-up that daily use of 600 mg of aspirin for a minimum of 25 months reduced the risk of CRCs by almost 60% in individuals with LS. Like other studies of aspirin use on cancer risk, cumulative use seemed to make a difference in the study because a reduced risk became evident over time. The optimum dose and duration of use of aspirin in individuals with LS still need to be established, but based on this evidence, many clinicians are considering aspirin therapy as chemoprevention in this population.

60 Cancer of the Rectum

Steven K. Libutti, Christopher G. Willett, Leonard B. Saltz,
and Rebecca A. Levine

INTRODUCTION

Information concerning epidemiology and systemic approaches to the management of both colon and rectal cancer was given in another chapter in this book. This chapter will focus on issues unique to rectal cancer with an emphasis on radiation, combined modality therapy, and sphincter-preserving surgery.

ANATOMY

The anatomy of the rectum can be very confusing as there are differing definitions of the relevant landmarks. In the upper portion of the rectum, there are changes both in the musculature of the large bowel and in the relationship to the peritoneal covering that roughly coincide. In the lower portion of the rectum, the mucosal changes occur at roughly the same location as the anal sphincter.

The anatomy of the rectum is usually divided into three portions (Fig. 60.1). The lower rectum is the area approximately from 3 to 6 cm from the anal verge. The midrectum goes from 5 to 6, to 8 to 10 cm, and the upper rectum extends approximately from 8 to 10, to 12 to 15 cm from the anal verge, although the retroperitoneal portion of the large bowel often reaches its upper limit approximately 12 cm from the anal verge. In some patients, especially elderly women, the peritonealized portion of the large bowel can be located much lower than these definitions. The determination of the location of the boundary between rectum and sigmoid colon is important in defining adjuvant therapy, with the rectum usually being operationally defined as that area of the large bowel that is at least partially retroperitoneal.

Externally, the upper extent of the rectum can be identified where the tenia spread to form a longitudinal coat of muscle. The upper third of the rectum is surrounded by peritoneum on its anterior and lateral surfaces but is retroperitoneal posteriorly without any serosal covering. At the rectovesical or rectouterine pouch, the rectum becomes completely extra-/retroperitoneal. The rectum follows the curve of the sacrum in its lower two-thirds. It enters the anal canal at the level of the levator ani. The anorectal ring is at the level of the puborectalis sling portion of the levator muscles.

The location of a rectal tumor is most commonly indicated by the distance between the anal verge, dentate (pectinate or mucocutaneous) line, or anorectal ring and the lower edge of the tumor. These points of reference are all different for different individuals. Also, these measurements differ depending on the method of measurement. This can be important clinically, as the measurement from a flexible endoscopy can substantially overestimate the distance to the tumor from the anal verge or other landmark. The distance from the anal sphincter musculature is clinically of more importance than the distance from the anal verge, as it has implications for the ability to perform sphincter-sparing surgery. The lack of a peritoneal covering over most of the rectum is a major reason for the higher risk of local failure after primary surgical management of rectal cancer compared to colon cancer. The

mesorectum is usually used as the structure to define the extent of a total mesorectal excision (TME), with most of the perirectal fatty tissue and perirectal lymph nodes (LN) contained within its boundaries.

Lymphatic Drainage

The lymphatic drainage of the upper rectum follows the course of the superior hemorrhoidal artery toward the inferior mesenteric artery. Lymph nodes that are above the midrectum and therefore drain along the superior hemorrhoidal artery are often part of the mesentery that is removed during resections of the intraperitoneal portion of the colon. Lesions that arise in the rectum below approximately 6 cm are in a region of the rectum that is drained by lymphatics that follow the middle hemorrhoidal artery. Nodes involved from a cancer in this region can include the internal iliac nodes and the nodes of the obturator fossa. These regions deserve particular attention during the resection and irradiation of lesions in this location. When lesions occur below the dentate line, the lymphatic drainage is via the inguinal nodes and external iliac chain, which has major therapeutic implications, especially for the radiation fields. The corollary of this high risk of inguinal node involvement for the very low-lying tumors is that tumors located above the dentate line are at low risk of inguinal node involvement, and these nodes as well as the external iliacs do not need to be treated.

Bowel Function

Fecal continence is maintained through the function of both the sphincter mechanism and the preservation of the normal pelvic floor musculature, which creates a neorectal angle or rectal sling. The pelvic floor is composed of the levator ani muscles, which separate the pelvis from the perineum and ischioanal fossa. The urethra, vagina, and anus pass through the levator muscles.

Preservation of fecal continence during surgery for rectal cancer is therefore dependent on a thorough understanding of the anatomic relationships of the musculature and the sphincter mechanism. Maintenance of the sphincter apparatus without preservation of the muscular angles will not have the desired result. These anatomic constraints, especially with respect to lateral margins, make the use of adjuvant chemotherapy and radiation therapy critical to a successful surgical outcome. This is true from both an oncologic as well as a bowel function perspective.

Autonomic Nerves

The preservation of both bladder and sexual function depends on the surgeon's understanding of the autonomic nerve supply to the pelvic organs.^{1,2} The hypogastric plexus is formed from the sympathetic trunks as they converge over the sacral promontory. These sympathetic nerves are found beneath the pelvic peritoneum

Figure 60.1 Division of the rectum into upper, middle, and lower thirds.

along the lateral pelvic sidewalls lateral to the mesorectum. The second, third, and fourth sacral nerve roots give rise to parasympathetic fibers to the pelvic viscera. The parasympathetic fibers proceed laterally as the nervi erigentes to join the sympathetic fibers at the site of the pelvic plexus that is just lateral and somewhat anterior to the tips of the seminal vesicle in men.^{1,2} In order to preserve these structures and, therefore, sexual and bladder function, a sharp rather than a blunt technique should be used to dissect the mesorectum.³⁻⁶

STAGING

Standard clinicopathologic staging is the best indicator of prognosis for patients with rectal cancer. For rectal cancer, it is increasingly common to use clinical staging as the basis for the decision to initiate neoadjuvant chemoradiation therapy. Therefore, the accuracy of that initial staging is critically important, both for management and for prognosis. There have been a large number of studies that have evaluated other prognostic markers, including pathologic, socioeconomic, and molecular, as described more fully in Chapter 57. However, even though many of these appear to have prognostic value, there are none that are commonly used to define management. This is related to the large number of tests that could be used, the lack of standardization of these tests, as well as the lack of knowledge as to how to incorporate them into the patient management scheme. The molecular marker that has engendered the most interest is the deletion of 18q.⁷ These markers have been fully reviewed elsewhere.^{8,9}

The staging system that should be used in the evaluation of patients with rectal cancer is the American Joint Committee on Cancer/International Union Against Cancer TNM (tumor, node, metastases) staging system (fully described in Chapter 57), which has been recently revised to subcategorize patients with stage III (node-positive) tumors. The Dukes staging system or its multiple modifications has been used for many years, but provides less information than the TNM system and should not be used. There have been gradual changes in the TNM system that primarily reflect the stage grouping rather than the system itself. The other systems should be acknowledged for their historical interest and for initially defining many of the high-risk factors for this disease.

Patients now often have both a clinical (preoperative) stage, which may define the need for neoadjuvant therapy, and a

pathologic (postoperative) stage. Initial therapy with chemoradiation can produce substantial downstaging (approximately 15% of patients will have a pathologic complete response, and as many as 40% in those with more favorable tumors). While some believe that the degree of response to neoadjuvant therapy should alter subsequent treatment, and this is in fact an area of active investigation (see later discussion), the current standard of care dictates that all surgical planning and adjuvant therapy be determined based on the initial clinical stage regardless of tumor response. This guideline is based in part on the idea that a good tumor response locally to chemoradiation does not translate into reduced risk of having micrometastatic disease, and thus does not lessen the need for adjuvant postoperative chemotherapy. Whether this will continue to be true in the face of newer data and more aggressive neoadjuvant regimens remains to be seen. Numerous studies have indicated that tumor response to neoadjuvant therapy is an important predictor of multiple oncologic end points for patients completing the full course of multimodal therapy. Patients with pathologic complete response in particular demonstrate excellent long-term results, with local recurrence rates as low as 0.7%, and significantly improved disease-free survival (DFS) and overall survival (OS) compared to nonresponders at 5 years (odds ratio [OR] = 3.28 and OR = 4.33, respectively).¹⁰⁻¹² It is unclear at this time whether such a favorable outcome can be maintained should the course of treatment be altered based on postneoadjuvant reassessment.

Although it is not standard practice to alter treatment based on local response to neoadjuvant therapy, preoperative restaging prior to surgery may still be valuable not only as a prognostic predictor but also for detecting interval metastatic progression. Multiple studies recommend repeating serum carcinoembryonic antigen (CEA) levels, for example, between chemoradiation and surgery as this value as well as the pre- to posttreatment ratio may be more important in predicting survival than the initial measurement.¹³⁻¹⁵ In addition, Ayez et al.¹⁶ advocate restaging with chest and abdominal computed tomography (CT), as this changed management in 12% of their patients, and spared 8% from undergoing noncurative rectal surgery, due to new findings of progressive metastatic disease.¹⁶

The major change that has occurred in the newest version of the staging system is the acknowledgment that both the T stage and the N stage have independent prognostic importance for local control, DFS, and OS.^{17,18} Thus, for patients with N0 and N1 tumors viewed separately, the extent of the primary tumor in the

rectum is of additional prognostic importance. Patients with T1-2N1 tumors have a relatively favorable prognosis and an outcome superior to that of other stage III patients. In fact, patients with T3N0M0 disease (stage II) have outcomes slightly inferior to those with T1-2N1M0, demonstrating the independent prognostic importance of T stage. These distinctions may allow future decisions to be more individualized as to the adjuvant therapy required.

Although at one level staging is very straightforward, the actuality of proper staging is much more difficult as it relies on multiple quality control issues that can mislead the clinician regarding proper therapy. For instance, it has been well demonstrated that for patients with colon and rectal cancer who are pathologically staged as N0, the prognosis is markedly improved for those in whom more than 12 to 14 nodes were identified by the pathologist compared with those in whom fewer nodes were identified.¹⁹ This could be a surgical issue (fewer nodes were removed) or a pathologist issue (fewer nodes were identified), but it suggests that many patients were inappropriately understaged, which could result in inappropriate therapy. Others have shown that staging accuracy continues to improve as the pathologist recovers more nodes, with accuracy leveling off at approximately 12 to 20 nodes recovered.^{20,21} (See discussion in Chapter 57). In rectal cancer, however, N staging presents a particular challenge as there are often fewer LNs in the specimen and preoperative radiotherapy is thought to reduce that number even further.²²⁻²⁴ In fact, one recent report suggests that LN harvests <12 in pretreated specimens may be a marker of high tumor response and improved rather than compromised oncologic outcome. In this study of 237 patients, local recurrence rates were significantly higher in the LN >12 group as compared to those with “inadequate” LN retrieval (11% versus 0%; $p = 0.004$).²⁵ As with colon cancer, the percentage of positive nodes is likely of greater prognostic importance than total LN number (M. Meyers, 2007, personal communication).²⁶⁻²⁸ The same issue relates to T-stage determination. If the pathologist does not look carefully for evidence of extension of tumor through the muscularis propria, the patient can be understaged, resulting in inappropriate treatment. Close or positive circumferential margins are a poor prognostic factor, which can only be found if the pathologist assiduously evaluates the radial margins.^{29,30}

The standard staging procedure for rectal cancer entails a history, physical examination, complete blood cell count, liver and renal function studies, as well as CEA evaluation. The routine laboratory studies are quite insensitive to the presence of metastatic disease, but they are usually ordered as a screen of organ function prior to surgery or chemoradiation therapy. High CEA levels are associated with poorer survival (see Chapter 57) and give an indication as to whether follow-up CEA determinations are likely to be useful. A careful rectal examination by an experienced examiner is an essential part of the pretherapy evaluation in determining distance of the tumor from the anal verge or from the dentate line, involvement of the anal sphincter, amount of circumferential involvement, clinical fixation, sphincter tone, and so forth, and has not been replaced by imaging studies or endoscopy. Colonoscopy or barium enema to evaluate the remainder of the large bowel is essential (if the patient is not obstructed) to rule out synchronous tumors or the presence of polyposis syndromes.

Local staging is completed with one of two imaging modalities, endorectal ultrasound (EUS) or pelvic magnetic resonance imaging (MRI). Each provides similar overall accuracy in T and N determination, and each has its advantages as well as drawbacks. The decision of which to use generally depends on local institutional expertise and resource availability.

EUS defines five interface layers of the rectal wall: mucosa, muscularis mucosa, submucosa, muscularis propria, and perirectal fat, as shown in Figure 60.2. Rectal tumors are generally hypoechoic and disrupt the interfaces depending on the level of tumor extension. The accuracy of EUS depends heavily on the experience and skill of the operator. In experienced hands, EUS has an overall accuracy rate for T stage of 75% to 95% with an

Figure 60.2 Endorectal ultrasound of a T3 tumor of the rectum, extension through the muscularis propria, and into perirectal fat.

overstaging of approximately 10% to 20% in T2 disease because of an inability to distinguish a desmoplastic response and postbiopsy changes from local tumor invasion, and approximately a 10% rate of understaging because of an inability to detect microscopic tumor extension.³¹⁻³³

EUS is less accurate in determining N stage than for T stage, with an overall accuracy rate of 62% to 83%.^{31,32} Understaging occurs because many nodal metastases from rectal cancer are small, even micrometastatic, and not easily detected by EUS. In addition, some nodes are located beyond the range of the ultrasound transducer and thus cannot be seen during the procedure. Overstaging is often related to an inflammatory response, perhaps secondary to previous biopsy or manipulation. EUS is not accurate for determining tumor regression after preoperative radiation and chemotherapy, as inflammatory changes and scarring can persist in the rectal wall or in perirectal soft tissue and may not reflect persisting tumor. Newer ultrasound techniques, such as three-dimensional ultrasound, are being explored but have not yet made it into standard practice.

Endorectal coil MRI allows discernment of the layers of the bowel wall and is similar in accuracy to EUS. Thin-section pelvic MRI with a surface coil also allows one to visualize the mesorectal fascia and thus to predict the likely distance of the surgical resection margin when performing a TME. The MERCURY Study Group confirmed this key advantage of MRI in their landmark 2005 multicenter trial, where specificity for predicting clear margins in 408 patients with varying stages of rectal cancer was 92%.³⁴ Although there has been great interest in this technique since then, follow-up studies still show a disappointing overall accuracy for T and N staging, which fails to surpass EUS in experienced hands. In one study of 96 patients who had MRI followed by TME, of 22 patients classified as having T2 disease on MRI, 3 had T1 and 6 had T3 tumors. Of 61 patients classified as having T3 disease on MRI, 8 had T2 tumors and 2 had T4. Thus, 6 of 22 (27%) patients who might have benefited from preoperative therapy for T3 disease would not have received that therapy. Eight of sixty-one patients (13%) would have received preoperative treatment inappropriately based on the MRI T stage.³⁵ For nodal status, 8 of 33 MRI-positive nodes were clinically negative, and 7 of 57 MRI-negative nodes were pathologically positive.³⁶ The presence of nodal disease identified by

MRI is also primarily determined by size, so the accuracy is similar to that of CT (<80%), although defining node positivity based on irregular border or mixed signal intensity could help improve sensitivity and specificity.³⁵

While the accuracy of MRI in determining T and N stage is imperfect, newer studies have focused on other radiographic features that may prove more relevant to prognosis and treatment planning than the traditional American Joint Committee on Cancer classification. In addition to defining the circumferential resection margin (CRM) of a low rectal cancer, high-resolution MRI can be used to predict tumor regression grade (TRG) after neoadjuvant therapy. TRG in the surgical specimen is a measure of response to preoperative chemoradiation and has been shown to correlate strongly with OS and DFS. In the first prospective study to address MRI-predicted TRG, Shihab et al.³⁷ found this too was significantly associated with long-term outcomes. A prognostic role was also demonstrated for pretreatment MRI, specifically in the characterization of tumor invasion into the pelvic floor muscles. Based on these results, the authors postulate that MRI-defined factors may be extraordinarily useful for modifying treatment in both the pre- and postneoadjuvant settings.³⁷ Patel et al.³⁸ offer a similar conclusion in their subgroup analysis from the original MERCURY study, which likewise found MRI-predicted TRG and CRM to be significant prognostic markers.

Two studies have taken this issue a step further by investigating exactly how MRI parameters can and should alter therapy. In another extension of the MERCURY trial, Taylor et al.³⁹ identified patients with “good prognosis” MRI (as defined by predicted negative CRM, absence of extramural venous invasion, and T2/T3a/T3b regardless of N stage) and referred them directly for TME resection without chemoradiation. Survival and recurrence outcomes were highly favorable, suggesting that early MRI can improve patient stratification for more selective and appropriate targeting of preoperative therapy.³⁹ In the postneoadjuvant setting, MRI can be used to identify poor responders who may require alternative treatments or more radical resection such as the extralevator abdominoperineal approach described by Shihab et al.⁴⁰

Finally, pelvic MRI may also help predict which patients are at increased risk for distant synchronous metastases and would therefore benefit from more extensive pretreatment imaging such as positron emission tomography (PET)/CT or liver MRI. Hunter et al.⁴¹ found that adverse features demonstrated on pelvic MRI (extramural venous invasion, extramural spread of >5 mm or T4, involved CRM or intersphincteric plane for low tumors) were significantly associated with a higher incidence of distant metastases (OR = 6.0; $p < 0.001$). The authors recommend using MRI-based risk stratification to identify patients who may benefit not only from more meticulous staging but also from more aggressive treatment regimens.⁴¹

M staging for rectal cancer is determined in the same way as colon cancer: with a baseline CT scan to evaluate the chest, abdomen, and pelvis.⁴² There has been much debate about the relative value of CT versus MRI or PET, particularly in assessing the liver, without any clear resolution. This decision depends heavily on the institutional expertise and the equipment available.

CT has an overall sensitivity of 70% to 85%, which might be improved with multidetector-improved CT technology, although the data do not yet prove that contention.⁴³ MRI is superior in characterizing liver lesions and distinguishing cysts and hemangiomas from tumor, especially with the use of enhancement with gadolinium or other agents.⁴⁴ PET with [¹⁸F]fluorodeoxyglucose shows promise as the most sensitive study for the detection of metastatic disease in the liver and especially in abdominal LNs for which CT and MRI are relatively insensitive. In addition, a meta-analysis of whole-body PET showed a sensitivity of 97% and a specificity of 76% in evaluating for recurrent colorectal cancer.⁴⁵ However, PET is not standardly used in preoperative staging, or recommended by National Comprehensive Cancer Network guidelines, and the incremental gain from routine PET scan appears to be small.⁴⁶

A 2013 study has re-emphasized this point, reporting that preoperative PET/CT had no impact on disease management in 96.8% of enrolled patients and advocating against its routine use for primary staging.⁴⁷ PET is probably most valuable in restaging patients with recurrence or suspected recurrence to detect additional metastatic sites prior to attempted resection of metastatic disease.

SURGERY

The surgical management of primary rectal cancer presents unique problems for the surgeon based in large part on the anatomic constraints of the pelvis. The primary goal of achieving a complete oncologic resection must be balanced with the desire for optimal nerve and sphincter preservation, which can be quite challenging in such a confined space.

Stage I

The treatment of early-stage rectal cancer can be confusing as there are many approaches that can be used, and patient selection is critical to outcome. In addition, the risk of nerve injury and damage to the anal sphincter is substantial for low-lying tumors and must be taken into consideration, along with the desire not to have a permanent colostomy for early-stage disease. Thus, the options for these patients are primarily those of local therapies without abdominal surgery, abdominal resection of the rectum with anastomosis and retention of the anal sphincter, and abdominal-perineal resection. The last two options are discussed in detail in “Stages II and III Rectal Cancer.”

Small early-stage lesions of the rectum that are diagnosed on physical examination or by colonoscopy/proctoscopy can often be managed with local resection. Local resection can be performed colonoscopically (as described in the Chapter 57), or lesions can be removed via a transanal excision with the patient positioned in a prone or lithotomy position. Appropriate retractors can provide visualization, and resection should extend into the perirectal fat with a surrounding margin of normal tissue.⁴⁸ For selected T1 and T2 lesions without evidence of nodal disease, transanal excision often provides an adequate resection of the primary tumor mass and can spare the patient the morbidity of a more extensive rectal resection. However, it does not stage the nodal drainage areas and therefore cannot provide as complete staging and management of the tumor as a definitive resection. In the effort to minimize the risk of locoregional failure, criteria for local excision have been established: the tumor must be within 8 to 10 cm of the anal verge, be well or moderately well differentiated, encompass <40% of the circumference of the bowel wall, and contain no evidence of lymphovascular invasion on biopsy. For T2 lesions, local resection should be followed by adjuvant chemoradiation. While these criteria are not strongly evidence-based (and are evolving along with surgical technology), a growing body of literature supports this approach particularly for T1 lesions. In a review of 677 T1 and T2 cancers after TME, Saraste et al.⁴⁹ identified three significant risk factors for LN invasion (and hence relative contraindications for local excision): T2 stage (OR = 2.0), poor differentiation (OR = 6.5), and vascular infiltration (OR = 3.4) with likelihood of LN positivity ranging from 6% to 78% depending on how many were found. Further support for these criteria comes from a study of 25 high-risk T1 rectal cancers, half of which were treated by transanal excision only (due to comorbidities or patient refusal to undergo resection) and the remainder with immediate conventional reoperation after local excision. Local recurrence was significantly higher in patients undergoing local excision only (50% versus 7.7%, mean follow-up 62 months), and there was a trend toward decreased 5-year survival (63% versus 89%). There were no differences in age, gender, or tumor characteristics between the two groups.⁵⁰ On the other hand, for low-risk T1 lesions in

the prospective phase 2 Cancer and Leukemia Group B study, local excision alone was associated with low recurrence and good survival rates that remained durable with long-term follow-up. For T2 lesions, however, even with adjuvant therapy, the role of local excision is less clear, as Saraste et al.⁴⁹ would predict, these were associated with higher recurrence rates.⁵¹ Whether the addition of neoadjuvant therapy might be helpful is a focus of multiple investigations. The American College of Surgeons Oncology Group has published preliminary results from its recently completed phase 2 trial of neoadjuvant capecitabine, oxaliplatin, and radiation therapy followed by local excision for ultrasound T2 tumors (ACOSOG Protocol Z6041).⁵² The authors report that 49 of 77 patients were downstaged and 44% achieved a complete pathologic response (pCR). There was one positive margin and one patient with a positive node. Rates of treatment-related toxicity and perioperative complications were high, however, requiring dose reduction and potentially compromising response. Follow-up trials are planned to improve upon the therapeutic ratio of this approach and better evaluate long-term efficacy.⁵³ More long-term results are reported from another prospective trial that supports the role of local excision following neoadjuvant therapy in selected T2N0 lesions with favorable features. Lezoche et al.⁵⁴ randomized 100 patients to either endoluminal resection or to laparoscopic or open TME, following neoadjuvant chemoradiation. Downstaging and pCR rates were similar in both groups, occurring in 51% and 28% of patients, respectively. With a mean follow-up of 9.6 years, oncologic outcomes were also essentially equivalent—with similar local recurrence rates and incidence of distant metastases (8% versus 6% and 4% versus 4%, respectively) and no difference in DFS.⁵⁴

Performing a good transanal excision requires substantial technical expertise as the surgeon must retain control over the primary tumor and obtain adequate mucosal margins as well as deep resection into the perirectal fat. Once removed, the tumor must be well laid out for the pathologist so that all relevant margins can be properly evaluated. There is some experience using preoperative radiation therapy and chemotherapy for small lesions, but care must be taken to have the site of the primary tumor well marked with a tattoo if this approach is taken, as excellent regression could make identification of the primary site difficult.

Newer techniques for transanal excision, including transanal endoscopic microsurgery (TEMs) and transanal minimally invasive surgery, have recently gained popularity based on improved visualization of the lesion. TEMs makes use of a standard laparoscopic light source and monitoring system combined with specialized instruments and scopes. The technique allows for videoscopic magnification and the placement of instruments through an operating sigmoidoscope. TEMs and its counterpart transanal minimally invasive surgery, which uses the more basic single port laparoscopic technology, may be applied, in general, to the same patients who are candidates for traditional transanal resection. However, these methods are most useful for excising more proximal lesions that are beyond the reach of standard surgical instruments and too large for removal through a colonoscope. Preliminary data supports the role of TEMs in both benign and early-stage malignant lesions with improved margin negativity and DFS compared to transanal resection for T1 and T2 lesions in a recent report.⁵⁵ Another meta-analysis found significant reductions in morbidity and mortality compared to conventional surgery and equivalent 5-year survival rates for T1 tumors.⁵⁶ Studies that include T2 lesions and selective use of adjuvant therapy have demonstrated 5-year OS and cancer-specific survivals over 90%, with recurrence rates between 4% to 9%.^{57,58} Moreover, the TEMs procedure fairs quite favorably with respect to long-term quality of life and functional outcome as most defecatory parameters return to baseline by 5 years, according to prospective data.⁵⁹ Other reports are less encouraging with recurrence rates following TEMs resection as high as 30%,⁶⁰ and therefore close endoscopic surveillance is recommended.

Stages II and III Rectal Cancer

The primary treatment of patients with stages II and III rectal cancer (T3-4 and/or node-positive) is surgical. However, in contrast to the treatment of patients with stage I disease, there is a strong body of information to suggest that combined modality therapy with radiation therapy and chemotherapy should be used in conjunction with surgical resection. This conclusion is based on both patterns of failure data, which demonstrate a substantial incidence of local, regional, as well as distant disease failure, and the fact that this incidence of tumor recurrence at all sites is decreased with the use of trimodality therapy.

The desire when performing a resection for rectal cancer is to preserve intestinal continuity and the sphincter mechanism whenever possible while still maximizing tumor control. Therefore, careful preoperative screening is crucial in the determination of the location of the lesion and its depth of invasion. As previously described, it is convenient to think of the rectum as divided into thirds for the purposes of the evaluation and preoperative determination of the surgical approach for resection. The upper third of the rectum is often considered the region of large intestine from the sacral prominence to the peritoneal reflection. These lesions are in almost all cases managed with a low anterior resection in much the same way as a sigmoid colon cancer (see Chapter 57). An adequate 1- to 2-cm distal mucosal margin can be achieved for these lesions well above the sphincter mechanism, and intestinal continuity can be restored using either a hand-sewn technique or a circular stapling device inserted through the rectum.^{61,62}

Tumors in the middle and lower thirds of the rectum can be considered as lying entirely below the peritoneal reflection. The resection of these tumors can be challenging because of the confines of the pelvic skeletal structure, and the ability to perform a resection with an adequate distal margin is significantly influenced by the size of the lesion. Nevertheless, tumors of the middle third of the rectum in most cases can be safely resected with a low anterior resection, with restoration of intestinal continuity and preservation of a continent sphincter apparatus.

Lesions in the distal third of the rectum, defined as those within 6 cm of the anal verge, can present the greatest challenge to the surgeon with respect to sphincter preservation. This is often influenced by the extent of lateral invasion of the lesion into the muscles of the sphincter apparatus and how close distally the tumor is to the musculature of the anal canal. The abdominal perineal resection (APR) has historically been considered the standard treatment for patients with rectal cancers located within 6 cm of the anal verge. This procedure requires a transabdominal as well as a transperineal approach with removal of the entire rectum and sphincter complex. A permanent end colostomy is created and the perineal wound either closed primarily or left to granulate in after closure of the musculature.

Although an APR is associated with a relatively low rate of local recurrence, it is not without the obvious problems of the need for a permanent colostomy and loss of intestinal continuity and sphincter function. Therefore, intense interest has been focused on developing approaches to the resection of tumors in the distal third of the rectum that would both avoid local regional recurrence and preserve intestinal continuity and sphincter continence.

Traditionally, tumors within 1 to 2 cm of the dentate line—that is, those that can be removed with at least a 1-cm distal margin—have been considered candidates for sphincter preservation and restoration of intestinal continuity via a coloanal anastomosis, which is commonly protected by a diverting loop ileostomy that can be reversed in 6 to 12 weeks.^{63,64} Newer data suggest that when TME and preoperative radiotherapy are routinely employed, even smaller margins are acceptable without oncologic compromise, as long as they are microscopically negative.⁶⁵ In fact, one of the advantages of neoadjuvant therapy is thought to be an increase

in sphincter-sparing procedures due to reduction in tumor bulk, which would normally preclude identification of this slight but critical margin.^{63,66} A recent systematic literature review identified seven studies addressing this topic, most of which implemented pre- or postoperative radiotherapy, and three of which reported results related to a margin of <5 mm. There were no statistically significant differences in local recurrence rates regardless of margin status. This data contributes to the growing evidence that a 1 cm (or even 5 mm) margin may be unnecessary and, more importantly, that strategies employed solely to achieve this margin (such as an APR or intersphincteric resection [ISR] for distal T1 lesions) may in fact be unnecessary as well.⁶⁷

While controversial in the United States, ISR has been described extensively abroad as a method involving at least partial resection of the internal sphincter designed to improve margin status without sacrificing sphincter function.⁶⁸ Recently, a large systematic review addressed the efficacy of this approach, identifying 14 (mostly retrospective) studies with 1,289 patients who underwent both open and laparoscopic ISR. Median follow-up was 56 (range, 1 to 227) months. Overall oncologic outcomes did not appear to be compromised with R0 resection achieved in 97% and a mean local recurrence rate of 6.7% (range, 0% to 23%). In addition, mean 5-year OS and DFS rates were 86.3% and 78.6%, respectively. Functional outcomes, however, were widely variable with only 51.2% of patients reporting “perfect continence,” while an average of 29.1% experienced fecal soiling, 23.8% incontinence to flatus, and 18.6% complained of urgency.⁶⁹

It has been postulated that neoadjuvant chemoradiation, while improving locoregional control and rates of margin-negative resection, has a deleterious effect on long-term functional outcomes, particularly after surgery for ultralow tumors. However, a recent multivariate analysis did not support this in ISR cases, finding the only significant predictors of continence were distance of the tumor from the anal ring and distance of the anastomosis from the anal verge. There was also no difference with age or extent of internal sphincter resection.⁷⁰ Another report did find significant functional differences when comparing partial ISR (resection above the dentate line), subtotal ISR (resection at the dentate line), and total ISR (resection from the intersphincteric groove). Patients with more extensive sphincter resection had higher fecal incontinence scores, more frequent nocturnal leakage, and more problems with discrimination. In addition, manometric studies at 12 months showed greater reductions in mean resting pressure. Overall though, quality of life was maintained in the majority of patients and function improved over time in both studies.⁷¹

Chemoradiation should be used preoperatively when performing sphincter-preserving resections for T3 or T4 rectal lesions or for any node-positive disease stages II or III. There is some evidence that preoperative radiation results in less morbidity than postoperative radiation therapy when a coloanal anastomosis is planned. In a study of 109 patients treated with a low anterior resection and a straight coloanal anastomosis, those receiving preoperative radiation therapy had a lower incidence of adverse effects on anal function than those receiving postoperative radiation.⁷² The authors attributed this to sparing of the neorectum from these effects. Relative benefits and outcomes for preoperative chemoradiation versus postoperative chemoradiation will be discussed in detail in following sections.

Total Mesorectal Resection

The goal of the resection of rectal tumors is the removal of the tumor with an adequate margin as well as removal of draining LNs and lymphatics to properly stage the tumor and to reduce the risk of recurrence and spread. For lesions in the intraperitoneal colon, the lymphatics and vascular supply are found in the mesentery associated with that region of bowel.

Figure 60.3 Total mesorectal excision.

In the rectum, the mesorectum is the structure that contains the blood supply and lymphatics for the upper, middle, and lower rectum. Most involved LNs for rectal cancers are found within the mesorectum, with T1 lesions associated with positive LNs in 5.7% of cases, T2 lesions having positive LNs in 20% of cases, and T3 and T4 lesions having positive LNs in 65% and 78% of cases, respectively.⁷³

The anatomy and approach to mesorectal excision is depicted in Figure 60.3. This operation involves a sharp dissection occurring in an avascular plane between the fascia propria of the rectum and the presacral membrane, beyond the region where most of the nodes are located. After a TME, the specimen is typically shiny and bilobed in contrast to the irregular and rough surface after a blunt dissection, where much of the mesorectal fat is left behind. TME attempts not only to clear involved LNs but also to adequately manage the radial margins of the rectal tumor. These radial margins have been shown to be more important with respect to the risk of local regional recurrence than the distal mucosal margin.^{66,74} Distal mucosal margins of ≥ 1 cm are adequate for local control; however, the margin on the mesorectum should extend beyond the distal mucosal margin in order to ensure a successful surgical outcome.^{64,66} Numerous studies have demonstrated the benefit of TME, and it is now considered the standard of care for the surgical management of middle and lower third rectal cancers.^{5,75-77} Although some studies have suggested that an adequate TME might in and of itself be sufficient management for T2 and T3 rectal cancers, the majority of the literature still supports the use of adjuvant chemoradiation for stages II and III disease even when combined with TME.

Large studies of proctectomy with TME have demonstrated a reduction in the overall incidence of local recurrence to <10%.⁴ The consequences of TME can be impairment in erectile and bladder function because of disruption of parasympathetic nerves that are located in proximity to the mesorectum. Several authors have stressed the importance of the experience of the surgeon performing the procedure, and some have suggested specific techniques for monitoring modalities that can be used during this procedure to minimize morbidity.^{5,6} A careful understanding of the anatomy and adequate visualization during sharp dissection will

help in minimizing injury to the parasympathetic nerves and the consequent morbidity.^{3,4}

Adequate visualization in the deep pelvis can often be a challenge. This may be a situation where the visual magnification and ability to enter tight spaces that are unique to the laparoscopic approach may be an advantage. Several groups have demonstrated the feasibility of laparoscopic TME for low rectal cancer as part of a sphincter-preserving operation.⁷⁸⁻⁸⁰ Some of the larger series, while demonstrating that TME using laparoscopic techniques can be performed safely, do not have adequate follow-up to demonstrate whether there were any oncologic disadvantages to such an approach. Unfortunately, the prospective random assignment trial conducted in the United States to evaluate the role of laparoscopic surgery for colon cancer excluded patients with low rectal lesions. In addition, subgroup analysis from the UK CLASICC trial reported a 34% conversion rate and double the frequency of positive margins compared to open cases (12% versus 6%), prompting the authors to advise against routine practice of laparoscopic proctectomy outside of the research setting.⁸¹ While these results have raised serious concerns regarding oncologic outcomes, follow-up reports are more encouraging. Multiple single-institution experiences have now been published demonstrating not only similar surgical parameters (margin status, LN harvest numbers) but also comparable recurrence and 5-year survival data.⁸²⁻⁸⁶ Furthermore, in a study based on National Surgical Quality Improvement Program data from 5,420 patients, Greenblatt et al.⁸⁷ reported significant short-term advantages to laparoscopy, including decreased length of stay (5 days versus 7 days; $p < 0.0001$) and 30-day morbidity (20.5% versus 28.8%; $p < 0.0001$). Smaller randomized trials as well as two recent large meta-analyses of randomized controlled trials also support the oncologic equivalence of the two approaches, although short-term benefits are mixed.⁸⁸⁻⁹⁰ In 10-year follow-up data from a pooled analysis of three randomized controlled trials (including 136 laparoscopic and 142 open cases), continued long-term oncologic safety of the laparoscopic approach was demonstrated with no significant differences compared to open in terms of locoregional recurrence (5.5% versus 9.3%), cancer-specific survival (82.5% versus 77.6%), or OS (63% versus 61.1%). Additionally, there was a trend toward lower recurrence among stage III patients in the laparoscopic group (17.7% versus 25.3%), though this did not reach statistical significance.⁹¹ Lujan et al.⁹² also reported similar rates of local recurrence and OS in a prospective cohort of 4,405 patients but found decreased complication rates (38.3% versus 45.6%) and improved oncologic parameters with laparoscopy, including decreased margin involvement and more complete TME. Finally, in a smaller study by Westerholm et al.,⁹³ laparoscopic surgery was found to be an independent predictor of DFS on multivariate analysis with 5-year DFS rates of 50.3% compared to 71.0% after open resection. Definitive recommendations await the results of three ongoing multicenter phase 3 randomized trials: the European COLOR II, the Japanese JCOG 0404, and the ACOSOG Z6051 from the United States.⁹⁴

While laparoscopic TME may be technically feasible, it requires a high level of expertise and can be particularly challenging to perform within the confines of a deep and narrow pelvis. More recently, robotic technology has been applied to rectal dissection, overcoming many of the limitations associated with conventional laparoscopy including limited dexterity, inadequate visualization, and tremor. Robotic surgery offers the advantages of a stable, three-dimensional image, enhanced ergonomics and articulating instruments with seven degrees of freedom, in addition to operator-controlled camera and retraction.⁹⁵ Embraced by urologists and gynecologists over the past decade, this technology is ideally suited to pelvic procedures and has the potential to yield enhanced oncologic and functional outcomes in rectal cancer surgery as well. Limited studies so far have demonstrated feasibility and acceptable short-term outcomes.⁹⁵⁻⁹⁹ In a case-control analysis of 118 patients undergoing laparoscopic versus robotic resection, Kwak et al.¹⁰⁰ reported no differences in surgical oncologic

parameters, postoperative complications, or recurrence rates at a median of 15 months follow-up. When compared to open TME in another case-matched study, the robotic approach was superior in terms of LN harvest, distal margin length, blood loss, and length of stay.¹⁰¹ Other potential benefits include decreased conversion rates in three large meta-analyses as well as a trend toward reduced anastomotic leaks and CRM positivity with complete autonomic preservation in a recent systematic review of 1,549 patients.¹⁰²⁻¹⁰⁵ Whether this data will translate into meaningful long-term advantages that justify the significantly higher cost of this approach remains to be seen.

The Robotic versus Laparoscopic Resection for Rectal Cancer (ROLARR) trial is a prospective, randomized, controlled, multicenter superiority trial that began enrollment in 2010, with a target recruitment of 400 patients. It will evaluate differences in conversion rates; CRM positivity, 3-year local recurrence, DFS and OS, as well as operative morbidity and mortality, quality of life, and cost-effectiveness. Investigators also wish to explore the purported clinical benefits of robotics including preservation of normal bladder and sexual function. Results from this ambitious trial are anxiously awaited.¹⁰⁶

Resection of Contiguous Organs and Total Pelvic Exenteration

Although aggressive surgical approaches to rectal cancer have resulted in improvement in locoregional recurrence rates, these rates can still be as high as 33%. Not infrequently, large rectal lesions will invade through the wall of the rectum into contiguous structures such as the bladder, prostate, vagina, and uterus. Carefully selected patients with recurrent or locally advanced rectal cancers may benefit from an aggressive approach such as a total pelvic exenteration. Local recurrences remain localized to the pelvis in a significant number of patients, with autopsy studies demonstrating the incidence of pelvic recurrence to be as high as 50%.¹⁰⁷

Recurrences in the pelvis can result in significant morbidity such as tenesmus, pain, bowel obstruction, and fistula. Although some of these can be ameliorated with radiation, these problems are best managed by preventing their occurrence. Although the impact of total pelvic exenteration on survival has been debated, the potential benefits on controlling locoregional disease and preventing morbidity keeps this technique as one of the tools in the surgeon's armamentarium when approaching large rectal lesions.

Existing literature on multivisceral resection of both primary and recurrent tumors has been recently evaluated in a systematic review of 22 studies comprising 1,575 patients. The authors reported a 4.2% perioperative mortality rate with morbidity of 42.5%. The overall 5-year survival rate was 50.3% with, not surprisingly, worse outcomes in patients with recurrent compared to primary disease (19.5% versus 52.8%). R0 resection was achieved in 79.5% of cases and, also not surprisingly, was the strongest factor associated with long-term survival.¹⁰⁸ Another review focusing only on locally recurrent tumors, reported R0 resection rates from 30% to 45% and 5-year global survival ranging from 30% to 40%, with authors stressing the importance of careful patient selection.¹⁰⁹ To this end, a panel of 36 colorectal surgeons were recently recruited to establish a scoring system for determining patient suitability for pelvic exenteration. A comprehensive list of clinicopathologic and radiographic criteria were considered and ranked by importance and utility in predicting negative resection margin. The authors hope to apply this quantitatively toward improving outcomes for this highly invasive and morbid intervention.¹¹⁰

For symptomatic tumors that are not resectable, other palliative options to consider include debulking and ablation. Ripley et al.¹¹¹ reported some benefit associated with sequential open radiofrequency ablation and surgical debulking in 16 patients, achieving a median survival of 12 months, with OS 24% at 36 months, and 3 patients remaining with no evidence of disease at 9,

48, and 84 months. There were four cases of significant postoperative morbidity, however, and variable levels of symptom relief.¹¹¹ Pusceddu et al.¹¹² reported far better palliation with CT-guided radiofrequency ablation in 12 patients with painful pelvic recurrence. At the end of follow-up (23 ± 23 months), 92% of patients were symptom free, with a 16% treatment-related morbidity (one rectovesical fistula and one rectal abscess).¹¹² Finally, transrectal high-intensity focused ultrasonography has now been described in the palliative treatment of rectal cancer. As the only completely noninvasive thermal therapy, it can be delivered by either an intracavitary or extracorporeal device, causing focal ablation via coagulative necrosis. In the first case report, it was well-tolerated and led to immediate symptom relief.¹¹³

Combined Modality Therapy (Stage II and III)

The use of adjuvant radiation therapy is based on the substantial incidence of locoregional failure with surgical therapy alone. Older studies demonstrate local failure rates of up to 50% in patients with T3-4 or node-positive disease (Table 60.1).¹¹⁴⁻¹²⁰ The locoregional recurrence rates in these studies are in the range of 25% to 50% for patients with T3-4 and/or node-positive disease and is a dominant pattern of failure, although distant recurrence is also of great importance. Local failure is related not just to the stage of the disease, but also the location of the tumor in the rectum (tumors located low in the rectum have a higher incidence of local failure) and the experience and ability of the surgeon. However, the relevance of these older local recurrence data has been brought into question with the advent of the use of TME, as previously described. It is important to realize that the data on local recurrence after primary surgical resection come from selected series with operations performed by experienced surgeons who have been specially trained in TME and may not be relevant to the operations performed by general surgeons who perform the operation only occasionally and who are not specially trained.

Although initial studies reported locoregional failure rates of <5% after TME without the use of any adjuvant therapy,^{75,77,121-123} there was concern that these excellent results could not be replicated in larger population-based studies. A number of European countries or regions have shown that the overall locoregional

recurrence risks could be decreased by limiting the surgeons who were authorized to perform rectal surgery to those who were trained and certified in the procedure, and by having educational sessions for those who were performing the surgery.⁵ This raised the question of what is the true rate of local failure after TME to help define which patients really require adjuvant therapy.

The most important analysis on local recurrence rates with TME are the data from the Dutch TME study in which patients were randomized to receive either TME alone or a short course of preoperative radiation therapy followed by TME.⁷⁷ All patients with rectal cancer were eligible, including those with early-stage disease. Special attempts were made to have good surgical and pathology quality control. The early results (2 years) relating to local tumor recurrence have been reported and are summarized in Table 60.2. The study demonstrates that there are subsets of

patients in whom TME alone is likely sufficient for obtaining good pelvic control, including patients with high rectal tumors (some of these may have been sigmoid cancers, rather than rectal) and low-stage tumors (T1-2, N0). On the other hand, low-lying rectal tumors that are moderately advanced (T3-4 and/or node-positive) had a higher incidence of locoregional failure. Local failure after TME alone was 15% in node-positive patients at 2 years, not corrected for site of the primary, and longer-term follow-up will undoubtedly demonstrate higher local failure rates. In addition, as these results were obtained in a controlled setting, one would likely not obtain similarly good results when surgery is done with less careful quality control. There was a consistent decrease in local failure rate by the addition of preoperative radiation therapy, but the absolute magnitude of the effect varied by the tumor characteristics previously discussed. Long-term results from the Dutch TME study have now been published demonstrating a stable, persistent >50% reduction in recurrence risk for the radiotherapy group after a median follow-up of 12 years. For patients with a negative circumferential margin, the benefit was even greater, with the 10-year cumulative incidence of local recurrence 3% after radiotherapy versus 9% after surgery alone ($p < 0.0001$) and the incidence of distant recurrence 19% versus 24% ($p = 0.06$). In addition, the incidence of cancer-specific death at 10 years was 17% for the irradiated group versus 22% for surgery alone ($p = 0.04$). OS rates, however, were equivalent.¹²⁴

A trial similar to the Dutch TME study was recently reported. This phase 3 trial randomized 1,350 patients with operable adenocarcinoma of the rectum to short-course preoperative radiotherapy (25 Gy in five fractions; $n = 674$) or to initial surgery with selective postoperative chemoradiotherapy (CRT; 45 Gy in 25 fractions with concurrent 5-fluorouracil [5-FU]) restricted to patients CRM involvement ($n = 676$). The primary outcome measure was local recurrence. At the time of analysis, 330 patients had died (157 preoperative radiotherapy group versus 173 selective postoperative CRT), and median follow-up of surviving patients was 4 years. A total of 99 patients developed local recurrence (27 preoperative radiotherapy versus 72 selective postoperative CRT). A reduction was noted of 61% in the relative risk of local recurrence for patients receiving preoperative radiotherapy (hazard ratio [HR] = 0.39; 95% confidence

interval [CI] = 0.27 to 0.58; $p < 0.0001$) and an absolute difference at 3 years of 6.2% (4.4% preoperative radiotherapy versus 10.6% selective postoperative CRT; 95% CI = 5.3–7.1). A relative improvement in DFS of 24% for patients receiving preoperative radiotherapy (HR = 0.76; 95% CI = 0.62 to 0.94; $p = 0.013$), and an absolute difference at 3 years of 6.0% (77.5% versus 71.5%; 95% CI = 5.3 to 6.8) was observed. OS did not differ between the groups (HR = 0.91; 95% CI = 0.73 to 1.13; $p = 0.40$). These findings provide further evidence that short-course preoperative radiotherapy is an effective treatment for patients with operable rectal cancer.¹²⁵

The data are excellent that radiation therapy, especially when combined with chemotherapy, can decrease the local failure rate. This is shown by a Swedish study of preoperative radiation therapy compared with surgery,¹²⁶ the Dutch TME trial in the preoperative setting,⁷⁶ and by multiple studies in the postoperative setting.^{127–132} There are also excellent data to show that locoregional failure is decreased by the use of radiation therapy and is further decreased by the use of concurrent 5-FU-based chemotherapy (Table 60.3).^{127,128,133} Most studies have demonstrated that local failure decreases by about 50% with the use of adjuvant radiation therapy, with a greater effect when concurrent 5-FU is used with irradiation. This appears to provide a strong justification for the use of adjuvant radiation therapy. What is less clear is whether trimodality therapy with radiation therapy improves survival, if radiochemotherapy should be given preoperatively or postoperatively, and precisely which patients should be irradiated. To that effect, Schrag et al.¹³⁴ investigated the use of a neoadjuvant chemotherapy utilizing a 5-FU-leucovorin-oxaliplatin (FOLFOX)-based regimen, with selective use of chemoradiation therapy only in those patients who had failed to demonstrate tumor improvement on neoadjuvant chemotherapy. Of the 30 patients treated without radiation therapy in this small pilot trial, none experienced local recurrence with a minimum follow-up of 4 years.¹³⁴ Three patients experienced distant failure, all in the lungs. This interesting pilot trial has led to the current phase 3 cooperative group trial comparing this approach of neoadjuvant chemotherapy plus selective use of radiation versus standard neoadjuvant chemoradiation therapy. Pending any new information from this randomized trial, neoadjuvant chemoradiation therapy remains appropriate standard practice.

DOES ADJUVANT RADIATION THERAPY IMPACT SURVIVAL?

Although there have been multiple randomized trials addressing the use of adjuvant radiation therapy or chemoradiation therapy, and although they consistently show an improvement in local control with adjuvant radiation therapy, the survival outcome data have been mixed. In the past, there have been two meta-analyses performed.^{135,136} Table 60.4 shows the results of a meta-analysis by Camma et al.¹³⁶ showing a decreased local recurrence rate, cancer mortality rate, and overall mortality rate with the use of preoperative radiation therapy, although without a decrease in distant metastasis rate. The Colorectal Cancer Collaborative Group study (Table 60.5) demonstrates no improvement in the likelihood of curative surgery with preoperative therapy or of OS with all types of radiation therapy combined.¹³⁵ Preoperative radiation therapy, however, was shown to improve local control, DFS, and OS compared with surgery alone, although deaths within the first year after surgery were higher after radiation therapy. Local recurrence with preoperative radiation therapy was 46% lower than surgery alone, and cancer deaths were decreased from 50% to 45%. Postoperative radiation therapy was shown to improve local control (although less than preoperative therapy), but did not impact long-term survival. Lending substantial strength to the conclusion that there was a true advantage to radiation therapy is the fact that there was a dose response demonstrated for the radiation effect on local control (i.e., better control was obtained with higher radiation dose). This observation strengthens the conclusion, as it demonstrates a direct correlation between the amount of therapy and outcome. The data from this analysis are heavily influenced by the results of a single Swedish study that showed a long-term survival advantage to the use of preoperative radiation therapy compared with surgery alone.¹²⁶ Thus, these data show that improving local control

with the use of radiation therapy (and presumably with concurrent chemoradiation therapy) is beneficial, and that trimodality therapy, especially when chemoradiation therapy is used preoperatively, can improve survival.

PREOPERATIVE RADIATION THERAPY

The second issue of importance is whether adjuvant therapy should be given preoperatively or postoperatively and the exact timing of the chemotherapy. Current data clearly favor the preoperative approach.

Perhaps the most important study addressing the issue of pre- versus postoperative adjuvant therapy is a German trial of preoperative versus postoperative chemoradiation with radiation therapy given at 1.8 Gy per fraction and using continuous-infusion 5-FU chemotherapy as a 120-hour infusion, for which results have been reported by Sauer et al.¹³⁷ This study demonstrates an advantage in sphincter preservation with the use of preoperative therapy. Of the patients thought to need an APR at initial assessment, only 19% had a sphincter-preserving surgery when operation was done immediately versus 39% after preoperative radiation therapy, although there was no difference in the overall sphincter preservation rate. There was a statistically significant decrease in local failure with preoperative radiation therapy compared to postoperative treatment (6% versus 13%; $p = 0.006$). The relative risk of local failure in the pre- versus postoperative treatment group was 0.46. The 5-year DFS showed a small advantage to preoperative therapy (68% versus 65%; $p = 0.32$), which was not statistically significant. There was a decrease in late anastomotic strictures with preoperative therapy, and acute toxicity was also decreased by the use of preoperative radiation and chemotherapy, both statistically significant. This provides strong evidence of the superiority of preoperative adjuvant treatment in patients in whom it is determined that adjuvant therapy is needed. Eleven-year follow-up data for this study have just been published, demonstrating a persistently significant improvement in local control for pre- versus postoperative chemoradiation (local relapse rates 7.1% versus 10.1%; $p = 0.48$). However, there was still no effect on OS or distant metastases, highlighting the need for more effective systemic therapy than just 5-FU-based regimens.¹³⁸

As multimodality treatment regimens are intensified to achieve even better outcomes, it is important to identify subgroups of patients at higher risk for severe toxicity and treatment interruption, both through investigation of predictive markers as well as attention to basic clinical parameters. In an unplanned analysis of the German trial data, Wolff et al.¹³⁹ found female gender to be significantly associated with CRT-induced acute toxicity but also associated with improved 10-year OS (62.7% versus 58.4%; $p = 0.066$). Men with no acute organ toxicities had much poorer OS compared to the rest, leading the authors to conclude that acute toxicity was a significant prognostic parameter and possibly a surrogate for treatment response. Future efforts will need to focus on mitigating this toxicity in susceptible patients without compromising treatment intensity.¹³⁹

Similar to the goals of the German trial, the National Surgical Adjuvant Breast and Bowel Project (NSABP) R-03 trial compared neoadjuvant versus adjuvant CRT in the treatment of locally advanced rectal carcinoma. Patients with clinical T3 or T4 or node-positive rectal cancer were randomly assigned to preoperative or postoperative CRT. Chemotherapy consisted of 5-FU and leucovorin with 45 Gy in 25 fractions with a 5.40-Gy boost within the original margins of treatment. In the preoperative group, surgery was performed within 8 weeks after completion of radiotherapy. In the postoperative group, chemotherapy began after recovery from surgery but no later than 4 weeks after surgery. The primary end points were DFS and OS. A total of 267 patients were randomly assigned to NSABP R-03. The intended sample size was 900 patients. Excluding 11 ineligible and 2 eligible patients

without follow-up data, the analysis used data on 123 patients randomly assigned to preoperative and 131 to postoperative CRT. Surviving patients were observed for a median of 8.4 years. The 5-year DFS for preoperative patients was 64.7% versus 53.4% for postoperative patients ($p = 0.011$). The 5-year OS for preoperative patients was 74.5% versus 65.6% for postoperative patients ($p = 0.065$). A pCR was achieved in 15% of preoperative patients. No preoperative patient with a pCR has had a recurrence. The investigators concluded that preoperative CRT, compared with postoperative CRT, significantly improved DFS and showed a trend toward improved OS.¹⁴⁰

In addition to improving survival, another reason for using preoperative chemoradiation therapy is to increase the chance for sphincter preservation for patients with low-lying tumors of the rectum, where an abdominoperineal resection would be conventionally used. The NSABP R-03 trial was able to obtain worthwhile information regarding this issue. When a patient was first seen, the surgeon was asked (for both preoperative and postoperative patients) what operation was needed. In the patients randomized to postoperative radiation therapy (i.e., immediate surgery), the determination in the office corresponded extremely well to the operation actually performed. However, in the patients who received preoperative radiation therapy, sphincter-preserving surgery was done in 50% of patients compared with 33% of those who had initial surgery.¹⁴¹ However, the data have been inconsistent overall in demonstrating an advantage to preoperative therapy in terms of sphincter preservation. The analyses are complicated because the decision as to whether sphincter-preserving surgery should be done is heavily dependent on the biases of the surgeon. If the surgeon believes that the same operation should be done regardless of tumor regression, then clearly the same surgery will be done. There are some surgeons who will do sphincter-preserving operations after preoperative irradiation, when they would not have done so if the surgery had been done first.

If one is using preoperative radiotherapy to try to improve the likelihood of sphincter preservation, the radiation must be given in such a way as to maximize the likelihood of this occurring. Specifically, a "standard" long course of irradiation to a dose of approximately 50 Gy at 18 to 20 Gy per fraction over 5 to 5.5 weeks (as given in the German trial mentioned previously) has been thought by most US investigators to be optimal. The short-course therapy with immediate surgery (typically 50 Gy for five fractions given over 1 week), as often used in Europe, followed by immediate surgery is not likely to produce enough tumor shrinkage to allow for sphincter preservation in patients with very low-lying tumors. Bujko et al.¹⁴² have published data that suggest that the short course is as effective in producing local control as the longer course of therapy. A total of 312 patients were randomized to either 25 Gy in 5 fractions followed by surgery within 1 week, or 50.4 Gy in 28 fractions with concurrent bolus 5-FU and leucovorin and surgery 4 to 6 weeks later. DFS was respectively (short- versus long-course therapy) 58.4% versus 55.6%; local recurrence, 9% versus 14.2%; severe late toxicity, 10.1% versus 7.1%; and acute toxicity, 3.2% versus 18.2%. There was no improvement in sphincter preservation with long-course treatment. Although this was a relatively small study, it provides important evidence to support the value of short-course preoperative therapy. A second randomized trial from the Australian Intergroup randomized 326 patients with T3 rectal cancer within 12 cm of the anal verge to short-course radiotherapy (25 Gy in five fractions) or CRT (50.4 Gy with continuous infusion 5-FU). Both arms received adjuvant chemotherapy. The primary end point, locoregional recurrence at 3 years, was not significantly different at 7.5% for short-course radiotherapy and 4.4% for CRT with no difference in distant recurrence rates or OS. At median follow-up of 6 years, there were no differences in late toxicity rates.¹⁴³

Both the Polish and Australian Intergroup trials were relatively small and not powered to show equivalence of long-course CRT and short-course radiotherapy. Both trials have relatively short follow-up and, as indicated by other randomized trials, locoregional

recurrence continues to increase with time. In addition, late toxicities may manifest many years following treatment.

Another question is whether the time interval between radiation and surgery is more important than the duration of the preoperative treatment itself. Pettersson et al.¹⁴⁴ evaluated 112 patients who underwent short-course radiotherapy (25 Gy over 5 to 7 days) with delayed surgery >4 weeks and found a significant downstaging effect not previously seen with immediate resection.¹⁴⁴ Another study in which 154 patients receiving short-course radiation were prospectively randomized to immediate surgery (7-day to 10-day interval) versus delayed (4 weeks to 5 weeks) also demonstrated a higher downstaging rate in the latter group (13% versus 44.2%; $p = 0.0001$). In addition, there was reduced systemic recurrence (2.8% versus 12.3%; $p = 0.035$) and a trend toward improved 5-year survival (73% versus 63%). Interestingly, however, delayed surgery was not associated with superior locoregional control or increased rates of sphincter-saving procedures and curative resections.¹⁴⁵ Further trials are necessary to determine the ideal schedule of radiotherapy and surgery that optimizes both downstaging and overall oncologic outcomes. Some clinicians are advocating even more extended intervals between radiation and surgery. In a review of 1,593 patients, the median interval from the start of radiotherapy was 14 weeks (range, 6 weeks to 85 weeks; interquartile range, 12 weeks to 16 weeks) with the highest pCR rate found in patients undergoing resection at 15 weeks to 16 weeks (18%; $p = 0.013$).¹⁴⁶

There are theoretical reasons to believe that radiation therapy delivered preoperatively would decrease the toxicity of therapy. With postoperative radiation therapy, the soft tissues of the perineum are at risk for involvement after an APR because of surgical manipulation and, therefore, need to be irradiated with its attendant acute skin toxicity. This is not needed with preoperative therapy. With postoperative radiation therapy, normal bowel is moved into the pelvis for the anastomosis after a low anterior resection and therefore is irradiated and at risk for late toxicity. In the preoperative setting, much of the irradiated bowel is removed with the surgical specimen and therefore is not at risk for producing late bowel injury. There is also likely to be a higher risk of having small bowel fixed in the pelvis after surgery secondary to adhesions, which could also lead to late toxicity. On the other hand, many studies have demonstrated that acute surgical morbidity and mortality are not substantially increased with the use of preoperative irradiation, although many surgeons routinely perform a temporary diverting colostomy in order to avoid the problems associated with an anastomotic leak. Except for the German trial previously mentioned, which shows decreased acute and late toxicity, data on late toxicity are not available to directly compare the two techniques when used with concurrent chemotherapy and the commonly used dose/fractionation schedules.

To better evaluate the impact of preoperative chemoradiation on long-term functional outcome, Loos et al.¹⁴⁷ performed a systematic review and meta-analysis of 25 studies and 6,548 patients, including six randomized controlled trials and previously published data from the Dutch TME trial. Although there was substantial heterogeneity of the included trials and low methodologic quality, the authors suggest that preoperative treatment has a largely negative impact on long-term anorectal function but does not significantly affect sexual or urinary performance compared to surgery alone. Without better designed trials, however, that include standardized pre- and postoperative assessment of these parameters as well as direct comparison to postoperative treatment, no definitive conclusions can be drawn.¹⁴⁷

As the retrospective meta-analyses have generally shown better tumor control locally and better evidence of a survival advantage secondary to preoperative irradiation, many gastrointestinal oncologists prefer preoperative CRT for the patient who clearly requires adjuvant radiation therapy. A reasonable strategy at present is to use preoperative CRT for patients in whom there is little doubt about the advisability of adjuvant therapy (T3 node-positive

or T4 disease) or patients with low-lying tumors in whom an APR may still be avoided, but to use initial surgery for other patient cohorts, with postoperative CRT used based on the operative and pathologic findings.

Another issue of importance is the timing of chemotherapy. It has been assumed by many investigators that concurrent preoperative chemotherapy and postoperative adjuvant chemotherapy is the proper way of delivering treatment. A study by the European Organization for Research and Treatment of Cancer, however, questions these assumptions.¹⁴⁸ Patients were randomized to receive either preoperative radiation therapy alone, preoperative CRT, preoperative radiation therapy and postoperative chemotherapy, or preoperative CRT and postoperative chemotherapy. Chemotherapy was bolus 5-FU (350 mg/m² per day for 5 days) and leucovorin (20 mg/m² for 5 days) with two cycles given with radiation therapy and four cycles postoperatively for the appropriate groups. Local recurrence rates were roughly similar for all patients receiving chemotherapy regardless of timing (7% to 9%) and significantly improved compared with those patients not receiving any chemotherapy (17%). There was no difference in survival outcomes based on the timing of chemotherapy. The 5-year DFS rates were 52.2% and 58.2% in the no adjuvant treatment groups and the adjuvant treatment groups, respectively ($p = 0.13$).

Two recent Cochrane reviews have addressed the role of adding chemotherapy to preoperative radiation regimens. The first included six randomized controlled trials, with a total of 247 patients, comparing preoperative CRT to radiation alone in the treatment of stage III cancers. Thirty-day mortality, sphincter preservation rates, and late toxicity events were similar between groups. A significant increase in acute grade 3/4 toxicity was seen in patients who received CRT versus radiation alone. While there was no difference in OS, CRT was associated with significantly less local recurrence (OR = 0.56; $p < 0.0001$).¹⁴⁹ A second meta-analysis, including five randomized controlled trials, addressed similar questions in stage II-III disease and reported similar findings. The addition of chemotherapy increased grade 3/4 toxicity with no impact on postoperative mortality, anastomotic leak rate, or sphincter preservation. There was also a significant reduction in 5-year local recurrence rate (OR = 0.39 to 0.72; $p < 0.001$) as well as an increase in pCR (OR = 2.12 to 5.84; $p < 0.00001$) in the CRT group, but again no differences in survival. Additional studies with longer follow-up are needed to determine the full benefit of preoperative chemotherapy as well its impact on functional outcome and quality of life.¹⁵⁰

WHICH PATIENTS SHOULD RECEIVE ADJUVANT THERAPY?

For either pre- or postoperative therapy, the physician needs to address the issue of precisely which patients need to receive adjuvant radiation therapy and chemotherapy. At the present time, these two modalities have been completely linked in US clinical trials, so it is not possible to determine if there are subsets of patients who might benefit from one modality and not the other. In addition, recent US trials have all used chemotherapy concurrent with the radiation therapy in addition to post-radiation chemotherapy, so it is not possible to determine the relative importance of each modality.

Based on the historical patterns of failure data, which demonstrated high local failure rates with surgery alone for patients with T3 and/or node-positive disease, virtually all US studies have evaluated this entire patient population. However, many of these studies predate the routine use of now-standard TME surgery, and more detailed analyses have allowed us to define characteristics that help define relatively low-risk and relatively high-risk patient subsets. As mentioned earlier, among the patients conventionally treated with adjuvant CRT, a number of relatively lower risk categories have been identified. Those include patients with T3N0 or

T1-2N1 disease,^{17,18,151} those with primary tumors located high in the rectum, those with wide circumferential margins on the final pathology specimen,^{29,30} those with node-negative disease after multiple (12 to 14 or more) nodes have been evaluated,^{19-21,152} and those in whom TME surgery had been performed by an experienced colorectal oncologic surgeon.^{153,154} In the preoperative setting, only some of this information will be available at the time a therapeutic decision must be made, but some information will be available (including knowledge of the surgeon). In addition, one must consider the known inaccuracy of transrectal ultrasound in staging and the experience of the ultrasonographer.^{33,60} However, if most of these conditions are met, it is possible that routine adjuvant radiation therapy, and perhaps chemotherapy, is not required for the lower-stage tumors.

Another question is which patients are unlikely to respond to chemoradiation at all and would only be disadvantaged by the toxicities and delay in surgical treatment. Numerous biomarkers and tumor-related features are under investigation as potential predictive factors of response, and this will have important implications for preoperative patient selection as well.¹⁵⁵⁻¹⁶⁵ Among these biomarkers, KRAS has received quite a lot of attention, but results are conflicting. Previous reports suggest that mutated tumors are less likely to develop a pCR compared to wild-type. Duldulao et al.¹⁶⁶ has recently published follow-up data that support this (13% versus 33% pCR in KRAS mutant versus wild-type; $p = 0.006$).¹⁶⁶ However, a larger meta-analysis of eight series and 696 patients showed no association between KRAS status and pCR, tumor downstaging, or cancer-related mortality. Although limited by the heterogeneity of its included studies, this report highlights the need for caution when considering biomarkers in the context of clinical decision making.¹⁶⁷ Another newly described method for predicting response to neoadjuvant therapy involves measuring histologic changes in the tumor soon after the initiation of treatment. Suzuki et al.¹⁶⁸ evaluated biopsies obtained 7 days into the CRT course, comparing expression levels of various apoptotic markers and cellular changes to pretreatment findings as well as to the final surgical specimen. Markers and cellular features of apoptosis at 7 days were strongly correlated with pCR and tumor regression. This study offers another potential strategy for identifying patients who might benefit from early alternative interventions.¹⁶⁸ At the present time, most patients treated outside clinical trials that have T3-4 and/or node-positive disease should probably receive neoadjuvant CRT if there are no extenuating circumstances. However, for patients who meet the previously mentioned favorable criteria, especially those with high rectal T3 N0 tumors, avoiding neoadjuvant radiation therapy and perhaps chemotherapy can be considered. Clinical trials will need to be performed to help resolve which subsets of patients do not require routine adjuvant radiation therapy. New data suggests that for the subset of patients who are confirmed to be node-negative after neoadjuvant chemoradiation and curative surgery, little benefit may be derived from additional postoperative treatment. In two studies, long-term survival and recurrence outcomes were compared between patients with ypN0 rectal cancer who did and did not receive adjuvant chemotherapy. Overall, there was minimal difference between the two groups with prognosis primarily determined by pathologic stage.^{169,170} However, these nonrandomized data should be regarded as preliminary and hypothesis-generating; postoperative chemotherapy should be the default position in these patients, and deviations from this plan should only be made on an individual basis after a detailed review of the patient's comorbidities, relative risks, and benefits, and a detailed discussion of this with the patient.

Another important area of investigation is whether patients who have a complete clinical response to neoadjuvant therapy can be safely managed with a nonoperative, "watch and wait" approach. In other words, can the organ-preserving multidisciplinary algorithm, which is now the standard of care for anal cancer, be adopted for rectal malignancy as well? This "wait and see" approach was first seriously addressed in a seminal study by Habr-Gama et al.,¹⁷¹

which compared the outcomes of 71 clinically complete responders who were observed without surgery to a well-matched group of patients with pCR who were resected. After a mean follow-up of 57 months, there were no cancer-related deaths in the observation group and recurrence rates were extremely low regardless of treatment strategy.¹⁷¹ Another more recently published study from a different group reported similar results. In this report, 21 patients who achieved a clinical complete response were followed without surgery for a mean of 25 ± 19 months and compared to 20 patients who underwent resection with pCR.¹⁷² There was one local recurrence in the observed group, treated with local excision, and two deaths in the control group. In addition (not surprisingly) functional outcome was significantly better in the patients who did not undergo surgery. Despite the small sample size and short follow-up, these results lend further credibility to the “wait and see” approach in carefully selected patients with rectal cancer. A similar report from yet a third group noted that in 32 patients carefully selected over a 5-year period, with a median follow-up of 28 months, 6 patients experienced local recurrence (3 of whom also had distant recurrence), and all 6 patients were able to undergo resection of the recurrent primary to achieve local control. When compared in an exploratory analysis to a control group of patient treated in the same institution who had undergone resection and had been found to have a pCR, 2-year distant DFS and OS appeared to be similar. Of course, these numbers are small and nonrandomized, and follow-up is short; however, the experience further supports the investigation of selective nonoperative management in patients who achieve a clinical complete response.¹⁷³

Given continued improvements in adjuvant therapies as well as the increasingly sophisticated imaging modalities available for follow-up, a new organ-sparing algorithm for treatment warrants further consideration. At present such an approach outside a clinical trial represents a clear departure from standard practice, and should only be considered in a fully informed patient who is willing and able to comprehend and accept the inherent risks. Logically, this approach seems most appropriate for consideration in those patients with distal tumors, in whom either an APR or a low anastomosis with poor functional outcome would be required. As noted previously, PET scans have insufficient sensitivity and specificity to be relied on in terms of determining the presence or absence of a complete clinical response, and should not be used for this purpose.

One aspect of combined modality therapy, which is undergoing reconsideration at some centers, is the order of administration of modalities of therapy. As noted in detail previously, preoperative chemoradiation followed by surgery followed by postoperative chemotherapy is the most commonly used approach. The role of administering all therapy, both chemotherapy and CRT prior to surgery has become of increasing interest, however. Chau et al.¹⁷⁴ were the first to publish an experience using induction capecitabine plus oxaliplatin (Cape/Ox) for 3 months prior to radiation plus capecitabine in 77 patients with poor-risk rectal cancer.¹⁷⁴ The response rate to Cape/Ox chemotherapy alone was 88%, with 86% of patients achieving symptomatic relieve within a median of 32 days of starting therapy. Fernandez-Martos et al.¹⁷⁵ published a small randomized phase 2 trial in which a total of 108 patients with rectal cancer were randomly assigned to either standard order chemoradiation followed by surgery followed by Cape/Ox chemotherapy, or to Cape/Ox chemotherapy first, followed by surgery. As might be anticipated from the small size of this trial, there were no differences between the arms in terms of efficacy, with pCR rates and R0 resection rates being essentially the same; however, greater dose intensity of both oxaliplatin and capecitabine was achieved in the group receiving preoperative chemotherapy, and higher grades 3 and 4 adverse events were seen during postoperative versus preoperative chemotherapy. The toxicities and dose intensities during the combined CRT were essentially the same in the two arms. Subsequently, several other single-institution experiences with this total neoadjuvant approach

have been reported. Cercek et al.¹⁷⁶ reported a retrospective series of 61 patients who received some or all of their planned chemotherapy as initial treatment for rectal cancer. Of these 61, 19 (31%) had either a pCR (14 patients) or had a complete clinical response and elected to pursue nonoperative management (5 patients). Perez et al.¹⁷⁷ reported preliminary results of a prospective trial of this approach in 36 patients and concluded that a larger proportion of patients were able to complete all planned FOLFOX chemotherapy than would have been expected from postoperative administration. Given the expense of a large-scale trial of initial versus postoperative chemotherapy, it is clear that an adequately powered trial comparing these two approaches will never be done. The potential benefits of initial chemotherapy are several. Firstly, it allows for administration of full-dose chemotherapy earlier in the course of treatment and appears to permit greater dose intensity, which may improve treatment of distant micrometastases and so improve long-term outcome. It also allows for patients requiring temporary ostomies after resection to have those ostomies closed after only 2 months and to not have to tolerate chemotherapy during the time they have an ostomy. In addition, the approach of delivering all planned chemotherapy and radiation therapy preoperatively allows for a favorable platform from which to consider nonoperative management in carefully selected patients.

A critical component of the “wait and see” approach is the ability to accurately identify pathologic complete responders in the preoperative setting. While many strategies have been utilized toward this end, including endoscopic evaluation, imaging, and tissue biopsy, there is no consensus on the optimal method and each has significant limitations. Endoscopic evaluation and close surveillance have long been considered important tools for detecting residual or recurrent malignancy. A recent expert consensus article described the cardinal signs of incomplete tumor response: deep ulceration with or without necrosis, superficial ulceration or mucosal irregularity, a palpable nodule despite mucosal integrity, or significant stenosis.¹⁷⁸ Using these criteria, Smith et al.¹⁷⁹ reported that an endoscopic, or “clinically complete,” response was 90% predictive of pCR. Sensitivity of this assessment was low, however, with 61% of the pathologic complete responders demonstrating ultimately false signs of incomplete clinical response.¹⁷⁹

A variety of imaging modalities have been applied to evaluate tumor burden after neoadjuvant therapy as well. Most are limited by the inability to differentiate postradiation fibrosis from residual cancer cells. Guillem et al.¹⁸⁰ found PET and CT equally inadequate in distinguishing complete from partial pathologic responders in a prospective analysis of 121 patients. Among the 26 patients with a complete response, only 54% and 19% were correctly classified by PET and CT scans, respectively. And of the 95 patients with an incomplete response, 66% and 95% were appropriately recognized by these techniques.¹⁸⁰ Perez et al.¹⁸¹ also found PET/CT lacking in its ability to definitively identify pCR. In a series of 99 patients, imaging yielded 5 false-negative and 10 false-positive results, giving PET/CT a 93% sensitivity, 53% specificity, 73% negative predictive value, and 87% positive predictive value for the detection of residual cancer. Accuracy of PET/CT was 85%, which was inferior to that of clinical assessment alone at 91%.¹⁸¹ Much attention has focused on the role of MRI in evaluating tumor burden at all stages of rectal cancer management. Diffusion-weighted MRI has been particularly useful for predicting tumor response in multiple sites and has the advantage of providing a quantitative measurement (apparent diffusion coefficient), which can be tracked longitudinally and compared to pretreatment values. However, this modality is also limited in its ability to distinguish residual solitary tumor cells from a complete response.¹⁸²

Endoscopic biopsies seem to be the most unreliable measure of tumor response, with one study reporting a negative predictive value of 11% (only 3 of the 28 negative biopsies were associated an actual tumor-free specimen after definitive resection).¹⁸³ These disappointing results might be explained by the fact that residual

tumor cells do not necessarily reside in the most superficial layers of the bowel wall. In fact, Duldulao et al.¹⁸⁴ reports that, in analysis of 94 patients with ypT2-4 tumors, only 13% had cancer cells remaining in the mucosa and only 56% in the submucosa. The majority of tumor burden after neoadjuvant therapy appears to be located at the invasive front, or deepest layer of the bowel wall, suggesting that only a full-thickness or excisional biopsy could accurately detect residual malignancy.¹⁸⁴ The question then becomes where to perform this biopsy. In a recent study, Hayden et al.¹⁸⁵ found that a significant amount of “tumor scatter” occurs after neoadjuvant therapy, with 49.1% of cancer cells located outside the visible ulcer or deep to normal-appearing mucosa. Moreover, the mean distance of distal scatter was 1.0 cm from the visible edge to a maximum of 3 cm, indicating that neither gross ulceration nor the traditional 2 cm margin can be used to adequately guide biopsy or excision of the potential residual tumor.¹⁸⁵ Additionally, even if complete full-thickness excision of the tumor site and all remaining potential cancer cells within the bowel wall were accomplished, a sterile specimen does not guarantee complete nodal response. While the rate of LN involvement in patients with a ypT0 lesion is small, it is not zero (7.7% and 9.1% in recent reports), and therefore there is ultimately no conclusive method for determining a pCR short of total mesenteric excision.^{186,187}

CONCURRENT CHEMOTHERAPY

The use of adjuvant chemotherapy has centered on the use of 5-FU chemotherapy, although this drug has been in use for over 50 years and is not very effective for colon or rectal cancer. The initial trials of trimodality therapy in rectal cancer used bolus 5-FU at a dose of 500 mg/m² per day for 3 days during weeks 1 and 5 of the radiation therapy. This was the approach routinely used until the results of the North Central Cancer Treatment Group study testing the use of long-term continuous infusion 5-FU with postoperative radiation therapy (bolus 5-FU was used both before and after the radiation therapy) were reported.¹³³ This study demonstrated an advantage to continuous infusion 5-FU (only during radiation therapy) compared with bolus 5-FU in terms of local control, DFS, and OS. Because of this result and the encouraging results found with more aggressive therapy in colon cancer, it was logical to think that further intensification of chemotherapy would be of value both for local and systemic control.

Unfortunately, this expectation has not been borne out. Two large US Gastrointestinal Intergroup trials have been run testing intensification with either more aggressive 5-FU and leucovorin, additional continuous infusion 5-FU, and other combinations, with data demonstrating no advantage.^{188,189} Thus, we are left with evidence that continuous infusion 5-FU during radiation therapy is of value in improving local control, distant metastases, and survival, but no evidence that anything other than simple 5-FU or 5-FU plus leucovorin should be used during the chemotherapy portion of the therapy. As will be discussed in the following, at present we do not have compelling evidence that addition of other agents, such as oxaliplatin, irinotecan, bevacizumab, cetuximab, or panitumumab, should be included with fluoropyrimidines concurrently with radiation therapy.

In practice, most gastrointestinal oncologists now use capecitabine or continuous infusion 5-FU during radiation therapy. The 1,608-patient phase 3 randomized NSABP R-04 trial has definitively established that capecitabine is noninferior to infusional 5-FU when used concurrently with preoperative radiation therapy in patients with rectal cancer.¹⁹⁰ There were no statistically significant differences in pCR rates, rate of sphincter-sparing surgery, surgical downstaging, or treatment-related toxicities. This study also was a 2 × 2 randomization to include concurrent oxaliplatin with radiation therapy or not. This large

trial showed no benefit for the inclusion of oxaliplatin, with substantially increased toxicity in the oxaliplatin-containing arm. A large trial of capecitabine versus bolus 5-FU confirmed that capecitabine is noninferior to 5-FU in this setting. Final results from this trial are now published, demonstrating superior 5-year OS (76% versus 67%; *p* = 0.05) and 3-year DFS (75% versus 67%; *p* = 0.07) for patients who received capecitabine in both adjuvant and neoadjuvant cohorts. There were similar rates of local recurrence in each group (6% versus 7%), but fewer patients receiving capecitabine developed distant metastases (19% versus 28%; *p* = 0.04).¹⁹¹ These findings suggest greater systemic efficacy of capecitabine compared to bolus 5-FU and mirror the conclusions drawn from the most recent X-ACT trial data for stage III colon cancer. Long-term follow-up from this study over a median of 6.9 years demonstrated that capecitabine significantly improved both DFS and OS with a better overall safety profile than 5-FU/folinic acid in the adjuvant setting.¹⁹²

There has been greater interest in the use of oxaliplatin added to 5-FU and radiation therapy, although thus far the results have been disappointing. A phase 1/2 study performed by the Cancer and Leukemia Group B demonstrated the feasibility of concurrent oxaliplatin, 5-FU, and radiation therapy,¹⁹³ as did a German multicenter phase 2 trial,¹⁹⁴ and the previously mentioned Radiation Therapy Oncology Group randomized phase 2 trial.¹⁹⁵ The NSABP, as part of their R-04 trial, is doing a second randomization to the use of weekly oxaliplatin (50 mg/m² per day) with an evaluation of pCR and local control as end points. However, phase 3 results have begun to emerge, and they are not as encouraging as had been hoped.¹⁹⁶ The French ACCORD cooperative group reported a trial in which 598 patients with locally advanced rectal cancer were randomly assigned to preoperative treatment with 5 weeks of radiation therapy (45 Gy in 25 fractions) with concurrent capecitabine 800 mg/m² twice daily 5 days per week or the same regimen plus oxaliplatin 50 mg/m² once weekly.¹⁹⁷ There was not a statistically significant difference in the primary end point of the trial, the pCR rate, which was 13.9% without and 19.2% with oxaliplatin (*p* = 0.09). More preoperative grade 3–4 toxicity occurred in the oxaliplatin group (25% versus 1%; *p* < 0.001). There were no statistically significant differences between groups in the rate of sphincter-preserving operations (75%), and no differences in terms of rates of serious medical or surgical complications or postoperative deaths at 60 days (0.3%). The authors concluded that the trial did not support the addition of oxaliplatin to this regimen, and that oxaliplatin should not be used with concurrent irradiation in standard practice. They did not detect an improvement in the frequency of clear circumferential radial margins, and they speculated that further investigations are warranted in selected populations. Secondary end point data from this trial have just been published demonstrating no advantage in clinical outcomes with the addition of oxaliplatin either. At 3 years follow-up, there were no significant differences in local recurrence, OS, or DFS.¹⁹⁸

A large Italian cooperative group phase 3 trial reached a similar result.¹⁹⁹ A total of 747 patients were randomly assigned to either 5-FU infusion (225 mg/m² per day) concomitant with external beam pelvic radiation (50.4 Gy in 28 daily fractions) or the same regimen plus weekly oxaliplatin (60 mg/m² × 6). The primary end point was OS. Data are not yet mature for this end point; however, a secondary end point of primary tumor response to preoperative treatment, as well as toxicity data, have been reported. Overall grade 3–4 toxicity rates on treated patients (mainly diarrhea) were 8% without oxaliplatin and 24% in the oxaliplatin-containing arm (*p* < 0.001). Eighty-two percent of patients receiving oxaliplatin got five or more doses of this drug. pCR rates were 15% and 16% in the 5-FU only and 5-FU–oxaliplatin arms, respectively. The authors concluded that the addition of weekly oxaliplatin to standard 5-FU–based preoperative CRT significantly increases toxicity without affecting local tumor response. Survival data requires further maturation.

As a follow-up to the seminal publication by Sauer et al.,¹³⁷ another German trial has been initiated to better evaluate the integration of oxaliplatin into neoadjuvant and adjuvant regimens for rectal cancer. This randomized phase 3 study, entitled CAO/ARO/AIO-04, hopes to achieve an impact on DFS not seen in previous reports. Only preliminary data has been published thus far supporting the feasibility of an oxaliplatin-based regimen, with good compliance and acceptable toxicity and surgical morbidity. Interestingly, in an unplanned analysis, the pCR rate was found to be significantly higher in the oxaliplatin group compared to 5-FU alone (17% versus 13%; $p = 0.038$). Longer follow-up is needed to address the primary end point of DFS, and the finding must be considered in the context of the multiple negative trials regarding concurrent use of oxaliplatin and radiation therapy previously noted.²⁰⁰

Postresection use of adjuvant chemotherapy based on the results in colon cancer has become a widespread practice, with oncologists using primarily FOLFOX (biweekly oxaliplatin, 5-FU, and leucovorin; see Chapter 57) as the postradiation chemotherapy. This is based on the reasonable, albeit unproven, extrapolation from data showing that the addition of oxaliplatin to 5-FU/leucovorin improves DFS and OS in the postoperative management of patients with colon cancer (see Chapter 57). In addition to studies that have substituted fluoropyrimidines, there is also substantial interest in the use of other agents added to fluoropyrimidines with concurrent radiation therapy. There have been studies with the addition of irinotecan,²⁰¹ but because of the overlapping toxicity of diarrhea with radiation therapy and 5-FU, plus the demonstrated lack of efficacy of irinotecan in the adjuvant treatment of colon cancer, use of irinotecan in the combined mode has not been, and most likely ought not be, heavily pursued. A small randomized phase 3 study showed no benefit to addition of irinotecan to 5-FU/leucovorin in the nonradiation portion of the treatment.²⁰² The Radiation Therapy Oncology Group completed a small randomized phase 2 trial of concurrent capecitabine, irinotecan, and radiation therapy versus concurrent oxaliplatin, capecitabine, and radiation therapy.¹⁹⁵ Both on the basis of a lack of data supporting adjuvant irinotecan and a superior pCR rate in the oxaliplatin-containing arm, no further development of the irinotecan-containing schedule is planned.

As biologic agents have a substantial appeal when used in combination with conventional cytotoxics, they also have a large appeal in combination with radiation therapy. There is evidence for a beneficial effect of both cetuximab and bevacizumab when combined with cytotoxics in patients with metastatic colon and rectal cancer (see Chapter 57). There are good laboratory data demonstrating radiation sensitization when these (and similar) agents are used *in vitro*, and a substantial improvement has been shown in survival in patients with head and neck cancer when cetuximab is added to radiation therapy.²⁰³ Only preliminary studies have been done,²⁰⁴ but given the lack of encouraging complete responses and the negative results with cetuximab in adjuvant colon cancer (see Chapter 57), it is unlikely that there will be substantial further investigations in this area, and neither cetuximab nor panitumumab should be used in standard practice with radiation therapy for rectal cancer. Similarly, bevacizumab has failed to demonstrate a benefit in adjuvant colon cancer, and should not be used in the routine management of locally advanced rectal cancer.

The literature on this topic continues to grow with a number of new phase 2 trials reporting on the feasibility, safety, and even potential superiority of neoadjuvant regimens that incorporate these agents. Kim et al.²⁰⁵ found that adding cetuximab to preoperative radiotherapy with irinotecan and capecitabine was well tolerated in 39 patients and achieved a much higher pCR rate of 23.1%, compared to 10% to 15% with conventional 5-FU regimens. Pinto et al.²⁰⁶ reported a similarly improved pCR rate of 21.1% in the StarPan/STAR-02 Study, which evaluated panitumumab, oxaliplatin, and 5-FU with concurrent radiotherapy. While this did

not reach their anticipated goal, it was a substantial improvement over both 5-FU-only regimens and 5-FU/oxaliplatin combinations from previous reports. The high incidence of grade 3-4 diarrhea with one toxic death, however, mandates modification of this regimen in future trials.²⁰⁶

Most recently, in a study evaluating pre- and postoperative Cape/Ox regimens with and without weekly cetuximab, the addition of cetuximab significantly improved radiologic response as well as OS (HR = 0.27; $p = 0.34$).²⁰⁷ These results are tempered by the negative phase 2 trial of cetuximab in the adjuvant treatment of KRAS wild-type stage III colon cancer. Outside of a clinical trial, neither cetuximab nor panitumumab should be used in the adjuvant or neoadjuvant treatment of locally advanced rectal cancer.

The role of bevacizumab in neoadjuvant therapy is also promising, although dosing schedules, appropriate use of synergistic medications, and patient selection have yet to be defined. When combined with 5-FU ± oxaliplatin in the most recent studies, toxicity levels were manageable and pCR rates ranged from 13% to 36%. In addition, Spigel et al.²⁰⁸ reported an 85% 1-year DFS.^{209,210} However, the negative outcomes of bevacizumab trials in colon cancer adjuvant therapy have greatly dampened enthusiasm for pursuing this approach. Outside of a clinical trial, the use of bevacizumab in the adjuvant treatment of rectal cancer is not recommended.

SYNCHRONOUS RECTAL PRIMARY AND METASTASES

The use of pelvic radiotherapy in patients with synchronous presentation of primary and metastatic disease is controversial. Primary combination chemotherapy can provide substantial palliation and can be considered as initial therapy in many patients with rectal cancer and metastatic disease.²¹¹ Endoscopically placed expandable metal stents can be considered for palliation or protection from impending obstruction. Control of disease in the pelvis can have important implications for patient quality of life; therefore, combined modality therapy, including radiation, chemotherapy, and in some cases palliative surgery, can be appropriate, especially when extrapelvic metastatic disease is small volume and the patient's prognosis is favorable enough that pelvic complications could be anticipated as a long-term problem. No firm guidelines can be made in the management of these complex patients, and treatment decisions must be made on an individual basis.

MANAGEMENT OF UNRESECTABLE PRIMARY AND LOCALLY ADVANCED DISEASE (T4)

Although the majority of patients who present with stage II and III disease have primary tumors that are technically easily resectable, there are a group of patients who have T4 tumors with deep local invasion into adjacent structures, which makes primary resection for cure difficult, if not impossible. Some T4 tumors invade into the vagina, which is easily resectable, but others invade into pelvic sidewall or sacrum, where a complete surgical resection may be impossible (the coccyx and distal sacrum can be resected, if appropriate), and others invade into bladder or prostate, where a more extensive surgical resection can be done, but often at the expense of major morbidity or functional loss. Although there are few randomized trials to define optimal therapy in this group of patients, there are data suggesting that it is appropriate to treat these patients with preoperative radiation therapy combined with chemotherapy, in a manner similar to that described for T3 disease, generally with concurrent 5-FU-based chemotherapy. This

will often result in a good clinical response that will allow for a potentially curative resection to be performed. It is preferable to treat a patient preoperatively to try to avoid leaving residual disease rather than attempting to salvage a patient after a clearly inadequate operation.

The use of adjuvant radiation therapy in this clinical situation also allows for treatment of the lymphatics draining the locally invaded organ, such as the internal or external iliacs, that are not typically resected in a low anterior resection or APR, but which may be at substantial risk of secondary involvement from an invaded organ, such as the bladder. Although the definition of “unresectable” is very subjective, a number of studies have shown that preoperative radiation therapy can convert a substantial number of these patients to having resectable disease with substantial cure rates.^{212–215}

In a randomized phase 3 trial of 207 patients with locally non-resectable T4 primary rectal carcinoma or local recurrence from rectal cancer, patients received chemotherapy (5-FU/leucovorin) administered concurrently with radiotherapy (50 Gy) and adjuvant for 16 weeks after surgery (98 patients) or radiation therapy (50 Gy) alone (109 patients). The two groups were well balanced according to pretreatment characteristics. An R0 resection was performed in 82 patients (84%) in the CRT group and in 74 patients (68%) in the radiation therapy group ($p = 0.009$). Local control (82% versus 67% at 5 years; log-rank $p = 0.03$), time to treatment failure (63% versus 44%; $p = 0.003$), cancer-specific survival (72% versus 55%; $p = 0.02$), and OS (66% versus 53%; $p = 0.09$) all favored the CRT group. There was no difference in late toxicity.²¹⁶ Although the use of preoperative radiation therapy with concurrent 5-FU-based chemotherapy, as described earlier, appears of value in patients with locally advanced disease, there is still a substantial incidence of local failure. Therefore, a number of investigators have explored ways to increase the radiation dose to the highest risk region to try to improve local tumor control. Three main techniques have been used: supplemental postoperative external beam radiation boost, intraoperative electron beam radiation therapy boost, and intraoperative brachytherapy boost.

There are relatively few data on the use of postoperative external beam as a boost, largely because of concerns of normal tissue tolerance after the use of the relatively large fields delivered preoperatively, extensive surgical resection, and the prolonged delay between initial external beam therapy and the final boost after recovery from surgery. The two intraoperative techniques are philosophically the same, although the technique of radiation delivery is different. After a high dose (50 Gy) of preoperative CRT and then a 4- to 6-week break, surgical resection is performed, the extent of which depends on the location and extent of tumor. Areas considered at high risk for residual tumor are determined both by

the surgical findings and frozen section pathologic evaluation. For electron beam intraoperative radiotherapy, a treatment cylinder is placed over the high-risk region, often on a pelvic sidewall or the sacrum, and the cylinder is then aligned to the radiation machine, which is either in the operating room or in the radiation therapy department. The cylinder acts both to hold normal tissues outside the radiation beam and to confine the electron beam. The use of electrons allows the radiation oncologist to adjust the depth of penetration of the beam to conform to the local tumor extent. When using brachytherapy, carriers for the radioactive sources are placed over the high-risk region, and the radiation is then given either during the surgery (high-dose rate) or the radioactive sources are inserted approximately 5 days after surgery and left in place for 1 or 2 days (low-dose rate). In all situations, the radiation dose is in the range of 10 to 20 (most commonly 15) Gy when used as a boost to conventional therapy. In both approaches, care must be taken to ensure that normal tissues such as small bowel are out of the irradiated volume.

Techniques similar to this have been used for a number of years and have shown encouraging results, although formal randomized trials have not been performed. Data suggest fairly good levels of local control and long-term survival if a gross total resection can be accomplished, with poorer results if there is gross residual (Table 60.6).^{217–220} Use of intraoperative radiotherapy boosts often requires specialized radiation facilities and expertise as well as an experienced team of radiation oncologists, surgical oncologists, urologists, and plastic surgeons. Similar types of surgical and radiation therapy approaches can produce surprisingly good results. For patients who still cannot have a surgical resection performed, either because of the tumor extent or because of coexisting medical problems, attempts should be made to maximize palliation and perhaps local control. Boost doses of radiation are appropriately delivered to the residual tumor to doses of >60 Gy if sensitive normal tissues (primarily small bowel) can be removed from the radiation fields. Only a small percentage (5%) of patients with these advanced tumors will be locally controlled and cured by such an approach, but a substantial percentage will obtain good palliation.^{221–223}

RADIATION THERAPY TECHNIQUE

There have been primarily two dosing schemes for radiation therapy that have been used in the treatment of rectal cancer. In the preoperative setting, many European centers have favored a rapid short-course treatment of doses of approximately 25 Gy in five fractions followed by immediate surgery, whereas US centers have generally favored doses of 50.4 Gy given at 1.8 Gy per fraction

TABLE 60.6

Intraoperative Radiation Therapy for Locally Advanced Rectal Cancer^a

Resection	Mayo Clinic			Massachusetts General Hospital		
	No. of Patients	Local Failure (%)	Overall Survival (5 y) (%)	No. of Patients	Local Failure (%)	Disease-Specific Survival (%)
Complete resection	18 ^b	7	69	40	9	63
Partial resection	35	~20	~40	24	37	35
No resection	1	—	0	—	—	—
Total	56	16	46	64	—	—
Recurrent locally advanced tumor	42	40	19	—	—	—

^a External beam radiotherapy + resection + intraoperative radiotherapy, no prior radiation therapy.

^b Two additional patients with no tumor in specimen—both without any tumor recurrence. These are included in the totals.

with a delay of 4 to 8 weeks until surgery. As previously mentioned, an advantage of the long-course therapy is that it provides time to have tumor regression, which appears to facilitate sphincter preservation, although it is more expensive and time-consuming for the patient. In addition, there was substantial late toxicity from the short-course treatment in earlier series, although this was most evident when the radiation therapy techniques were less sophisticated and simple anteroposterior/posteroanterior fields alone were used, which were at times quite large²²⁴; those techniques are not used at present.

Although major late toxicity is relatively uncommon, functional gastrointestinal disturbances are relatively common. These relate to both surgical effects on bowel with lack of a good reservoir function and possible nerve dysfunction, as well as long-term radiation effects on bowel compliance and neural functioning.^{225,226} Many patients continue to have some rectal urgency and food intolerance (especially to roughage), but symptoms tend to improve over time and most patients can live a relatively normal life regarding their gastrointestinal tract. Detailed discussions with the patient about the type of foods likely to cause worsening bowel symptoms, attention to the superimposed problems that can occur from other difficulties such as lactose intolerance, and use of agents such as loperamide all can help the patient deal with bowel problems.

Small bowel–related complications are directly proportional to the volume of small bowel in the radiation field and the radiation dose. In patients receiving combined modality therapy, the volume of irradiated small bowel limits the ability to escalate the dose of 5-FU. A number of simple radiotherapeutic techniques are available to decrease radiation-related small bowel toxicity. First, small bowel contrast or CT scanning during treatment planning allows identification of the location of the small bowel so that fields can be designed to minimize its treatment. Multiple-field techniques (preferably a three- or four-field technique) are now standard to minimize normal tissue irradiation. The use of lateral fields for the boost as well as positioning the patient in the prone position can further decrease the volume of small bowel in the lateral radiation fields.

The treatment should be designed with the use of computerized radiation dosimetry and be delivered by high-energy linear accelerators that deliver a higher dose to the target volume while relatively sparing surrounding normal structures. The advantage of combining a multiple-field technique, high-energy photons, and computerized dosimetry produces a homogenous dose distribution throughout the target volume and minimizes the dose to the small bowel. Although not well studied to date, newer developments in intensity-modulated radiation therapy may allow more conformal radiation dose distributions and a decrease in the irradiation of small bowel. To date, intensity-modulated radiation therapy has not been shown to be of additional value in the adjuvant treatment of rectal cancer.

After pelvic surgery, the small bowel commonly fills the pelvis. Adhesions can form, resulting in fixed loops of small bowel in the radiation fields. In this situation, despite treatment of the patient in the prone position, the use of multiple-field techniques may be of limited value. In contrast, when radiation therapy is delivered preoperatively to a patient who has not undergone prior pelvic surgery, the small bowel is usually mobile. When no small bowel fixation is present, treatment in the prone position can exclude much of the small bowel from the posteroanterior field and completely from the lateral fields.

Various physical maneuvers to exclude small bowel from the pelvis have been examined. Gallagher et al.²²⁷ determined the volume, distribution, and mobility of small bowel in the pelvis after a variety of maneuvers. Regardless of the prior surgical history, a significant decrease was seen in the average small bowel volume when the patients were treated in the prone position with abdominal wall compression and bladder distention compared with the supine position. Treatment in the prone position without abdominal wall compression was not consistently effective in displacing

small bowel and, in some patients (most commonly, obese), the volume of small bowel increased.

Radiation Fields

The precise radiation fields that are used should depend on the individual clinical situation, although the principles of the radiation treatment remain the same. The locoregional failures in rectal cancer occur both because of residual disease in the soft tissues of the pelvis as well as from residual pelvic nodal disease. The nodal disease can be in the internal iliac chain for very low-lying lesions, but only involves the external iliac nodes if the anal canal or sphincter is involved or if an organ is involved that drains into the external iliac system. The internal iliac nodes are not usually dissected by the surgeon, so it is important to treat these for low rectal cancers, but the external iliacs should not be routinely irradiated. The proximal extent of nodal radiation is arbitrary, but the primary drainage of all rectal cancers is along the mesenteric system, and those nodes should primarily be treated surgically. Extending radiation fields to cover para-aortic nodes is not indicated unless there is evidence of disease in those chains.

Because many of the local recurrences occur in the soft tissues of the pelvis, the radiation oncologist must be sure to treat the regions that are least well treated by the surgeon. These include extension to the pelvic sidewall and presacral space, and to the prostate in men and vagina in women. The proximal extent of the radiation field should generally extend to the sacral promontory, as that is the level at which there is an attachment of the posterior peritoneum and where the retroperitoneal rectum becomes the intraperitoneal colon. Above this level, there is little risk of pelvic soft tissue invasion for standard rectal cancer.

The lower extent of the radiation field is more complex. Often, the surgeon will rely on the radiation oncologist to sterilize the most distal extent of the primary tumor in order to perform a sphincter-preserving operation, so the distal margins should be at least a couple of centimeters below the primary tumor mass. Although rectal tumors tend to have only a minimal amount of longitudinal spread along the mucosal margin, they can spread further distally in the perirectal fat and in the LNs in the mesorectum. In fact, this is part of the rationale for a TME. Attempts should thus be made for treatment to at least the level of the dentate line for most low-lying rectal cancers, although this is likely not necessary for rectal cancers in the proximal third. However, it is also likely true that a substantial part of the late toxicity from pelvic radiation therapy is related to dysfunction of the anal sphincter. Thus, it is important to try to minimize the amount of sphincter that is irradiated. Although many textbooks define the lower edge of the radiation field relative to the bones of the pelvis, this is not the proper way to think about irradiating such tumors. The locations of bony anatomic landmarks such as the ischial tuberosity have no consistent relationship to the anal sphincter, anal verge, dentate line, or the rectal cancer. The radiation oncologist must identify the location of these structures as best as possible using radiopaque markers and rectal contrast, and then determine the balance between adequate distal coverage of the tumor as well as minimizing irradiation of the anal sphincter and the perineum (acute toxicity). For anteroposterior or posteroanterior fields, the lateral borders should extend to treat the pelvic sidewall, a possible region for soft tissue extension. The lateral fields should have a similar superior and inferior margin. The posterior border should include all of the presacral soft tissue so the posterior extent of the field should cover the anterior border of the sacrum with at least a 1.5-cm margin for patient motion and dosimetric variation. The anterior border of the lateral fields should cover at least the posterior border of the vagina or the prostate, the anterior extent of the primary rectal tumor, and the anterior edge of the sacral promontory. Examples of typical radiation fields as depicted by a CT simulation are shown in Figure 60.4.

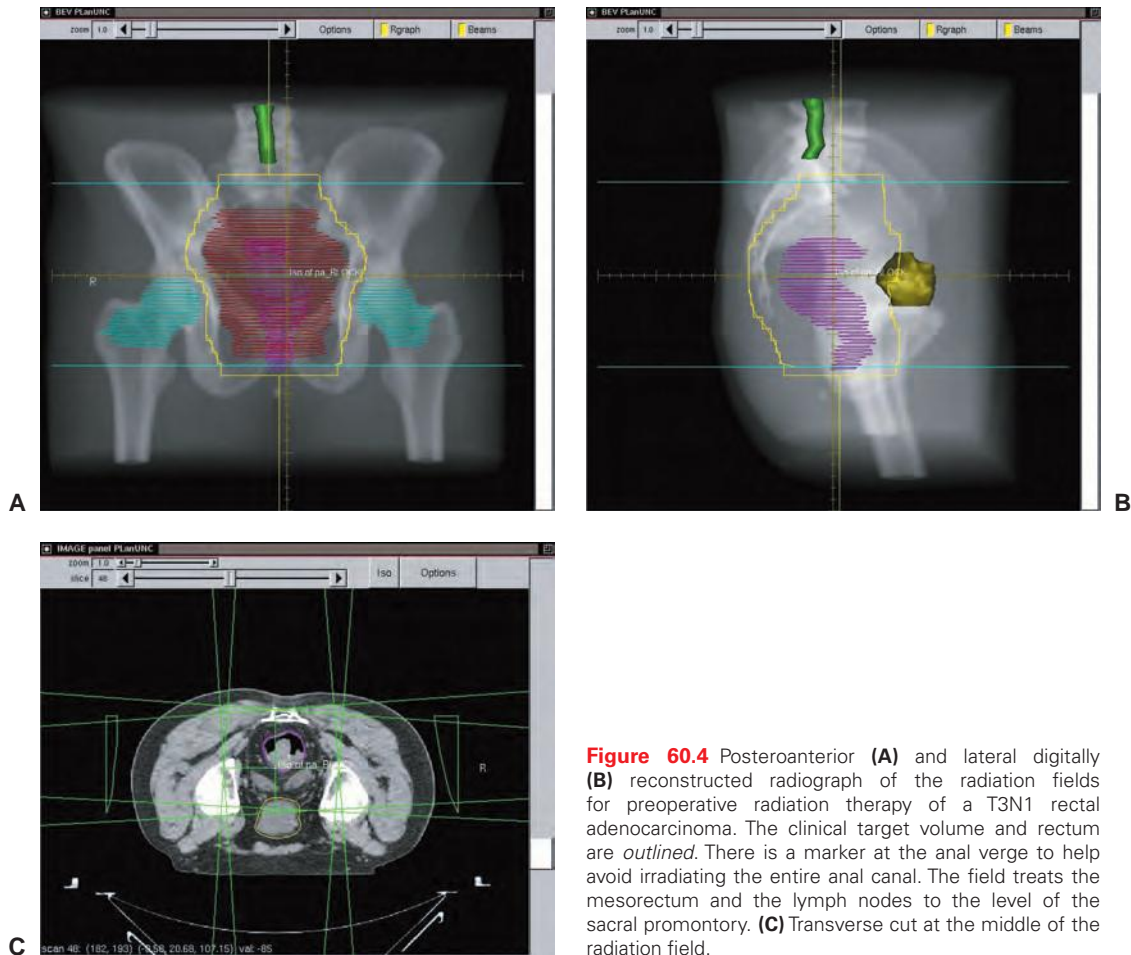

Figure 60.4 Posteroanterior (A) and lateral digitally (B) reconstructed radiograph of the radiation fields for preoperative radiation therapy of a T3N1 rectal adenocarcinoma. The clinical target volume and rectum are outlined. There is a marker at the anal verge to help avoid irradiating the entire anal canal. The field treats the mesorectum and the lymph nodes to the level of the sacral promontory. (C) Transverse cut at the middle of the radiation field.

INTRODUCTION

Carcinoma of the anal canal is a rare malignancy, although its incidence is steadily increasing. The development of anal cancer is a multifocal process largely associated with the human papillomavirus (HPV). The treatment approach to this disease has evolved significantly over recent decades and serves as a model for organ-preserving therapy, transitioning from radical surgery by abdominal perineal resection (APR, entailing permanent colostomy placement with associated high pelvic recurrence rates) to a nonsurgical approach of definitive chemoradiotherapy with 5-fluorouracil (5-FU) and mitomycin C (MMC), leading to successful preservation of anorectal function in the majority of patients. Anal cancer is relatively unique amongst gastrointestinal malignancies in that it has a low propensity for metastatic spread, making local-regional control a paramount endpoint in the approach to this disease. Over the past 2 decades, published randomized trials have demonstrated the superiority of chemoradiotherapy with 5-FU and MMC over radiation therapy alone, radiation with concurrent 5-FU, as well as induction cisplatin/5-FU alone followed by concurrent radiotherapy using the same regimen. Additionally, randomized trials have failed to demonstrate a definitive benefit for radiation dose escalation nor superiority when substituting cisplatin for MMC. Treatment with chemoradiotherapy is associated with significant acute and chronic toxicity rates, and improvement in radiation therapy techniques has been shown to decrease such. Current investigations include the use of novel cytotoxic and inhibitor targeted agents, including epidermal growth factor receptor, in efforts to improve outcomes in patients with more advanced disease, as well as further understanding the molecular etiology and resistance of this disease. This chapter provides an overview of the background, epidemiology, diagnosis, multidisciplinary treatment, and outcomes of tumors arising in the anal canal and perianal skin, as well as anal canal adenocarcinoma and melanoma.

EPIDEMIOLOGY AND ETIOLOGY

Anal cancer is the least prevalent among all gastrointestinal (GI) cancers. It has been reported that anal cancers account for 1% to 2% of all large bowel malignancies. According to the 2014 American Cancer Society statistics, about 7,210 men and women (37% men and 63% women, a ratio of almost 1:2 for men to women) will be diagnosed with anal cancer, and it is estimated that 950 (or 13%) of those diagnosed with anal cancers will die from their disease.¹

The median age at diagnosis for anal, anal canal, and anorectal cancers was 60 years during 2006 to 2010. This data showed that among all races, Caucasian females experienced the highest incidence rate (2.1 out of 100,000), whereas Asian males had the lowest incidence rate (0.5 out of 100,000) during that time frame (Fig. 61.1). The median age at death was 64 years during this period. It was estimated that African American males

and Caucasian females had the highest mortality rate (0.3 out of 100,000 each) among all races, whereas at the same time, both male and female Asians had the lowest mortality rate (0.1 out of 100,000 each) (see Fig. 61.1).

The incidence of anal cancer has been increasing over the last 30 years in the United States as well as globally.^{2,3} This is likely related to the increase in infections by the sexually transmitted HPV and HIV, which may have a significant impact on anal cancer incidence. In one large case-control series, an increasing number of sexual partners was associated with the development of anal cancer in both men and women (odds ratio of 4.5 for women and 2.5 for men with ≥ 10 sexual partners). This study also demonstrated that a history of anal warts was associated with a higher risk of developing anal cancer, as was receptive anal intercourse in women.³

Human Papillomavirus Infection

High-risk HPV type-16 has been detected in almost 90% of cases of squamous cell carcinoma of the anus.⁴ A recent meta-analysis suggests that HPV-16 is found more frequently (75%) and HPV-18 less frequently (10%) in anal carcinomas than in cervical carcinomas. Moreover, approximately 80% of anal cancers demonstrated more than one HPV genotype.⁵ Anal cancer, now considered to be a predominantly HPV-related cancer, has an incidence 15 times higher in homosexual men than in heterosexual men.⁶ In most cases, anal infection with HPV is sexually transmitted, and the risk for cancer is increased in patients with a history of receptive anal intercourse in women and homosexual activity in men.⁷ It is also been shown that women with high-grade cervical or vulvar dysplasia are more susceptible to develop anal cancer, as cervical or vulvar HPV infection escalates anal HPV infection risk.⁸

HIV Infection

The incidence of anal cancer in patients who are infected with HIV is estimated to be twice that of HIV-negative patients. Highly active antiretroviral therapy (HAART) has resulted in patients with HIV living longer and the development of related malignancies. In contrast to other HIV-associated malignancies, the incidence of anal cancer has actually risen following implementation of HAART.⁹⁻¹¹ According to the National Cancer Institute (NCI), the rise in anal cancer incidence rates during 1980 to 2005 was predominantly seen in male patients with HIV, relative to their female counterparts.¹² Although HIV has been considered to be a major factor in anal cancer incidence, it is also suggested that HIV may have an impact on the survival of patients with anal cancer, with one report demonstrating that HIV-positive patients with anal cancer tended to develop earlier recurrences than HIV-negative patients by 20 months, although the median survival for HIV-positive patients (34 months) and HIV-negative patients (39 months) were similar (non-significant) (discussed as follows).¹³

Figure 61.1 Anal cancer distribution among different races. (Top) Incidence rate. (Bottom) Death rate.

Other Risk Factors

According to the American Society of Colon and Rectal Surgeons (ASCRS), risk factors other than HIV and HPV infections include:

- Age: 67% >55 years.
- Smoking: There are reports demonstrating that smoking is a risk factor for anal cancer development. According to one study, the relationship between smoking and anal cancer persists for both gender types (adjusted odds ratio for women = 3.8, 95% confidence interval [CI], 2.3 to 6.2; adjusted odds ratio for men = 3.9, 95% CI, 1.9 to 8.0). Similarly, the risk of anal cancer appears to be related to the pack-year history of smoking, with more extensive histories associated with a higher risk.¹⁴
- Immunosuppression: Solid organ transplant recipients with chronic immunosuppressive therapy have a six times higher risk to develop anal cancer relative to the general population.¹⁵

Benign anal lesions are no longer thought to contribute to the development of this disease, although anal cancers are frequently misdiagnosed as these conditions.

SCREENING AND PREVENTION

Anal squamous intraepithelial lesions (SIL) or anal intraepithelial neoplasia (AIN) have been recognized as precursors that can progress to anal squamous cell carcinoma (SCC).¹⁶ Although there are no published guidelines that recommend screening of

the general population for anal cancer, there are high-risk groups that may benefit from such, most prominently patients infected with HIV. Although the natural history of SIL is still being unraveled, studies show increased rates of progression in HIV-positive patients with a relative risk of 2.4 and increasing to 3.1 for those with CD4 counts below 200.^{17,18} The rationale for screening for SIL is based on the following: there is a high incidence of the anal cancer within the proposed screening population (i.e., HIV-positive patients), available screening tests are effective and cost-efficient, and early detection can change the outcome of the disease. The initial recommended screening test is an “anal Pap smear” that evaluates cells in the anal canal for abnormal cytology through swabbing. Patients with abnormal cytology should then be evaluated by high-resolution anoscopy, which facilitates the visualization of abnormal lesions, allowing biopsy and/or removal.^{19,20} Algorithms for the management of low-grade and high-grade SILs remain controversial as more data are needed to determine the effectiveness of intervention on decreasing long-term rates of anal SCC.

Treatment options of high-grade AIN include ablation with electrocautery, topical trichloroacetic acid, topical 5-FU, or imiquimod,^{21–23} with estimated lesion control rates ranging from 60% to 80%. A 2012 Cochrane Review highlights the dearth of evidence addressing the efficacy of available interventions for SIL. This review resulted in one randomized trial being identified. This trial evaluated the medication imiquimod versus placebo. Although underpowered, results showed no statistically significant benefit for treatment. The authors concluded that, given the rising incidence of AIN and anal cancer, well-designed randomized controlled trials are urgently needed to address this topic, with emphasis on AIN resolution, downstaging, recurrence, and progression to invasive disease in both HIV-positive and -negative populations.²⁴

A promising strategy for the prevention of anal dysplasia and malignancy is HPV vaccination. Two vaccines (Cervarix and Gardasil) are now approved by the U.S. Food and Drug Administration and have been shown to protect against cervical cancer in women.^{25,26} The quadrivalent HPV vaccine Gardasil has demonstrated efficacy for prevention of HPV 6-, 11-, 16-, and 18-related genital warts and has been shown to protect against cancers of the anus, vagina, and vulva.²⁷ In a large, double blind study, 602 healthy men who have sex with men were randomized to receive the quadrivalent HPV vaccine versus placebo. With a 36-month median follow-up for the development of AIN and/or high-risk HPV infection, significantly reduced rates of high-grade anal dysplasia and high-risk HPV infection were demonstrated in the vaccinated group.²⁸ No cases of anal cancer or vaccine-related serious events were noted. In the context of limited availability and suboptimal outcomes of AIN screening programs, vaccination may reflect the best long-term approach for reducing anal cancer risk and is recommended for girls and boys at age 11 or 12 years and girls 13 to 26 years of age who have not been previously vaccinated.

PATHOLOGY

A variety of malignancies can arise in the anal canal and perianal skin. The typical gross appearance of SCC of the anal canal consists of a lesion with rolled edges, often with central ulceration, with a minority consisting of polypoid lesions (Fig. 61.2). On a practical level, these can be divided into squamous and nonsquamous histologies. The vast majority of anal canal tumors are classified as SCC, which encompasses tumors previously described as basaloid, cloacogenic, transitional, mucoepidermoid, and verrucous mucoepidermoid varieties (Fig. 61.3). These subtypes generally referred to tumors arising in the anal transitional zone, where the anal squamous histology transitions into the glandular epithelium seen in the colorectum. From a treatment standpoint, these are all approached as SCC. The current World Health Organization (WHO)²⁹ classification does not include these subtypes. The majority of these are

Figure 61.2 A 60-year-old male with advanced squamous cell carcinoma of the anal verge, exhibiting rolled edges with central ulceration.

Figure 61.3 A microscopic image of a biopsy revealing nonkeratinizing squamous cell carcinoma.

nonkeratinizing, although tumors arising below the dentate line often display keratinizing properties. Most squamous lesions are moderately to poorly differentiated and display koilocytic changes consistent with HPV infection.

It is believed that most anal cancers arise from precancerous changes (i.e., AIN) of the anal canal and perianal skin epithelium. AIN is a multifocal process associated with HPV, analogous to cervical dysplasia. There is a progression from normal epithelium to condyloma and grade I AIN (associated with mild dysplasia), later progressing to grade II AIN (with moderate dysplasia), and ultimately grade III AIN with severe dysplasia, as well as in situ disease. Once disease has reached grade III AIN, it rarely regresses. It has been estimated that approximately 5% of AIN III patients progress to invasive malignancy, often occurring over a multiyear period. This incidence of progression of AIN III is substantially increased in patients who are immunocompromised.^{17,30} The prevalence of AIN among HIV-negative homosexual men is high (>36%), and almost universal among HIV-positive men who have

sexual intercourse with men.³¹ The incidence of AIN is believed to be much greater in patients with HIV as exemplified by a French study analyzing 8,153 routine hemorrhoidectomy specimens, finding that only 3 cases of AIN (0.04%) were seen,³² as compared to 20 cases out of a 103 (19.4%) in specimens from HIV-positive men (Fig. 61.4).³³

Additional nonsquamous cell histologies arising in the anal canal include adenocarcinoma, small cell carcinoma/neuroendocrine tumors, as well as undifferentiated carcinomas, melanomas, and rarely, lymphomas and sarcomas. Neuroendocrine tumors are thought to arise from endocrine cells in the transitional zone and, like neuroendocrine tumors arising from other sites, tend to disseminate widely. A suspected anal adenocarcinoma may actually reflect an extension from a distal rectal adenocarcinoma in some situations. Mucinous adenocarcinoma is generally thought to arise

Figure 61.4 A schematic representation of an anal intraepithelial neoplasia progression. Note that the increasing severity as a proportion of epithelium is replaced by progressive increase in immature-appearing cells, ultimately leading to invasive disease with violation of the basement membrane. (Goldstone SE. Diagnosis and treatment of HPV related squamous intraepithelial neoplasia in men who have sex with men. *PRN Notebook* 2005;10:11–16.)

in the anal glands and ducts and is uncommon. It should be noted that histology is generally more important than location within the anal canal and usually dictates overall patient management.

Tumors of the perianal skin are similar to that seen in the anal canal, primarily comprised of SCC. These tumors are generally well differentiated and keratinizing. Verrucous carcinoma—also sometimes known as a giant condyloma or Buschke-Lowenstein tumor—was initially described in 1925. These tumors are sometimes mistakenly considered to be benign and misdiagnosed as condylomata acuminata, with a subsequent histologic analysis revealing invasion. These are often locally destructive and HPV related. They are often slow growing and can be present for many years before coming to medical attention. Local recurrence rates following excision are high and malignant transformation can be seen in up to 50%.³⁴ Additional precursor lesions seen in the perianal skin include Bowen disease, which consist of a slow growing intraepidermal SCC that may mimic perianal dermatitis, as well as Paget disease, which is similar to the entity seen associated with breast cancer, with an eczematous appearance. Approximately half of Paget disease patients will harbor an underlying adenocarcinoma, notably in the colorectum.

CLINICAL PRESENTATION AND STAGING

Symptoms of anal cancer can be diverse and include bleeding, pain, sensation of a mass, itching, anal discharge, tenesmus, and a sense of fullness or a lump in the anal canal. The most common presentation is bleeding from the anus. More extensive lesions may present with more ominous symptoms such as incontinence, passage of gas or stool from the vagina, or significant change in bowel habits. Less frequently, an enlarged inguinal lymph node is reported, and 20% of patients are initially asymptomatic. Symptoms may often be dismissed as hemorrhoids or other benign causes, and it is crucial to further evaluate by a physical examination and anoscopy. Any mass should be biopsied for a diagnosis.

Clinical staging is performed by a combination of clinical, endoscopic, and radiographic examinations (Table 61.1). History should include an assessment of anal sphincter function as well as HIV risk factors. Digital rectal examination can identify fixation to the sphincter complex or adjacent organs such as the vagina and prostate. Proctoscopy provides information about the extent of mucosal spread, including the relationship to the dentate line, and facilitates biopsy. It may be necessary to examine patients under anesthesia secondary to pain and sphincter muscle spasms. Female patients should undergo a gynecologic examination to determine vaginal involvement and to exclude other HPV-associated cancers, including evaluation of the cervix. Imaging is used to better delineate the local extent of disease and regional adenopathy, and to determine the presence of distant metastases. An endoanal

ultrasound or pelvic magnetic resonance imaging (MRI) can be considered to assess tumor size and involvement with local structures such as the anal sphincters and vagina or prostate. Computed tomography (CT) scans of the chest, abdomen, and pelvis are commonly employed to evaluate distant disease and adenopathy, particularly in the inguinal regions. Of all patients presenting with palpable inguinal lymph nodes, only 50% are malignant; therefore, fine-needle aspiration is often recommended in suspected cases, and a positive result may guide radiation field design and dose. Some oncologists have suggested a routine sentinel lymph node (SLN) evaluation as a staging technique. A systematic review of 16 published series evaluating the outcome of SLN biopsy of inguinal nodes included 323 patients, and the success in identifying the SLN was 86%. However, the exact role of SLN in the pretreatment evaluation remains undetermined.³⁵

A number of recent studies have investigated the role of positron-emission tomography (PET)-CT scans for staging anal cancer. One review described outcomes of patients undergoing conventional staging with ultrasound as well as PET-CT scans. Of 95 patients, the authors found that PET-CT scans were particularly valuable in detecting more extensive nodal and metastatic disease as well as the detection of synchronous malignancies. Upstaging was noted in 14% of patients, and 23% had a change in treatment plan relative to ultrasound staging.³⁶ Another study comparing the use of conventional imaging with CT scans and MRI found that the addition of PET-CT scans upstaged patients in 20%, downstaged 25%, and altered management in 37%. These authors concluded that PET-CT scans should be a routine part of initial staging of all anal cancers. A lesser impact was seen in patients evaluated in follow-up where PET-CT scans upstaged 11% and downstaged in 6% of cases; however, these changes also led to an altered management in 17%, indicating a potential role for selected PET-CT scan use when there is a question of recurrence or salvage surgery is planned.³⁷ A study by Vercellino and colleagues³⁸ similarly found that PET-CT scans were useful in the avoidance of unnecessary biopsies and surgery, with a negative predictive value of 94%, ultimately impacting on treatment plans in 22% of follow-up cases. Finally, PET-CT scans may have prognostic value as well, with one study demonstrating a significant correlation between metabolic response posttreatment and progression-free as well as overall survival.³⁹ National Comprehensive Cancer Network (NCCN) treatment guidelines include the use of FDG-PET scans with CT scans as part of the staging evaluation, notably for patients with T2-4N0 disease or those with involved lymph nodes.⁴⁰ After the previously mentioned evaluation, staging is assigned according to the American Joint Committee on Cancer 2010 (AJCC) (Table 61.2).

PROGNOSTIC FACTORS

Clinical

T and N stages are the most important prognostic factors for anal cancer. According to the AJCC, the 5-year observed overall survival (OS) rates of anal cancer for stage I, II, IIIA, IIIB, and IV are 69.5%, 68.1%, 45.6%, 39.6%, and 15.3%, respectively. It has also been demonstrated that the 5-year OS rates for T1, T2, T3, T4, N0, and node-positive anal cancer are 86%, 86%, 60%, 45%, 76%, and 54%.⁴¹

There are relatively few studies available that analyze prognostic factors for anal cancer. According to the Radiation Therapy Oncology Group (RTOG) 98-11 study, tumor size (>5 cm), involved lymph nodes (N+), and male sex were associated with worse 5-year disease-free survival (DFS) and OS.⁴² Results from European Organisation for Research and Treatment of Cancer (EORTC) 22861 study indicated that skin ulceration, lymph node involvement, and male sex were independent variables associated with local-regional failure (LRF) and OS in multivariate analysis.⁴³ A secondary analysis of the UK Coordinating Committee on

TABLE 61.1

Recommended Diagnostic Evaluation in Newly Diagnosed Anal Cancer

- Digital rectal examination with tumor characterization (location, fixation, extent)
- Examination of inguinal lymph nodes; consideration of biopsy if deemed suspicious
- Endoscopy/proctoscopy
- Gynecologic examination in females to rule out vaginal invasion as well as exclude gynecologic primary
- Positron-emission tomography/computed tomography (PET-CT) scan
- Complete blood count with serum chemistries as well as HIV testing/CD4 levels in the presence of risk factors

TABLE 61.2

TNM Anus Staging According to the American Joint Committee on Cancer

Primary Tumor (T)			
TX	Primary tumor cannot be assessed		
T0	No evidence of primary tumor		
Tis	Carcinoma in situ (Bowen disease, high-grade squamous intraepithelial lesion [HISL], anal intraepithelial neoplasia [AIN] II–III)		
T1	Tumor 2 cm or less in greatest dimension		
T2	Tumor more than 2 cm but not more than 5 cm in greatest dimension		
T3	Tumor more than 5 cm in greatest dimension		
T4	Tumor of any size invades adjacent organ(s) (e.g., vagina, urethra, bladder) (direct invasion of rectal wall, perirectal skin, subcutaneous tissue or sphincter muscle is not classified as T4)		
Regional Lymph Nodes (N)			
NX	Regional lymph nodes cannot be assessed		
N0	No regional lymph node metastasis		
N1	Metastasis in perirectal lymph nodes(s)		
N2	Metastasis in unilateral internal iliac and/or unilateral inguinal lymph node(s)		
N3	Metastasis in perirectal and inguinal lymph nodes and/or bilateral internal iliac and/or inguinal lymph nodes		
Distant Metastases (M)			
M0	No distant metastasis		
M1	Distant metastasis		
Anatomic Stage/Prognostic Group

From Edge SB, Byrd DB, Compton CC, et al., eds. *AJCC Cancer Staging Manual*, 7th ed. New York: Springer-Verlag; 2010: 171.

Cancer Research (CCCR) Anal Cancer Trial (ACT) 1 trial indicated that palpable lymph nodes as well as male sex portended a poor prognosis, similar to previous studies. In addition, after adjusting for these factors, these investigators also reported that lower hemoglobin and higher white blood cell counts were also prognostic in terms of anal cancer death and worsened overall survival, respectively. Tumor site, T classification, and platelet levels had no influence on outcomes.⁴⁴ However, not all studies have confirmed gender as an independent prognostic factor in terms of local control, metastasis, or overall survival.^{45,46}

Although well-differentiated histologies have been shown to portend more favorable outcomes in other cancers, the histologic subtypes of anal cancer have not yet been demonstrated as substantial prognostic factors.⁴⁷ According to a study by Schlienger and

colleagues,⁴⁸ there was no significant difference found in survival analysis among cloacogenic, well-differentiated, and moderately or poorly differentiated anal carcinomas.

Molecular

Prognostic biomarkers provide information on patient outcomes regardless of therapy, whereas predictive biomarkers provide information about the effect of specific therapeutic intervention.⁴⁹ The ultimate goal of determining prognostic factors is to improve patient survival. Disease processes and progression result from molecular and pathologic pathways, and by targeting altered pathways, potential avenues for therapeutic interventions that could facilitate improvements in survival may emerge. Similarly, molecular analyses of anal cancer to predict treatment response and survival outcomes are essential. Lampejo and colleagues⁵⁰ performed a systematic review on anal cancer prognostic biomarkers after reviewing 29 studies for final analysis. The authors found that 13 biomarkers were associated with anal cancer outcomes in only one study, whereas the tumor suppressor genes p53 and p21 as prognostic markers were established by more than one study.

The p53 gene is located in the short arm of chromosome 17 (17p13.1), which encodes a protein (393-amino acid nuclear phosphoprotein) that regulates the cell cycle and is responsible for cell apoptosis.^{51,52} Accumulation of nuclear proteins was seen by immunohistochemistry in the cases of muted p53 genes in some studies.^{53–55} These studies found that in anal carcinoma, p53 was overexpressed with a range of 34% to 100%. Wong et al.⁵² described that increased p53 expression was associated with worse local–regional control ($p = 0.02$) and DFS ($p = 0.01$). Another study of 64 patients suggested that mutant p53 was responsible for inferior LRF rates relative to wild type, although nonsignificant (48 versus 27%, $p = 0.14$).⁵⁶ Allal and colleagues⁵⁷ reported that anal cancer patients with p53-positive lesions had a lower local–regional control rate (relative risk [RR], 0.38; $p = 0.03$) and shorter DFS (RR, 0.29; $p = 0.003$).

The p21 gene protein, a cyclin-dependent kinase (CDK) inhibitor, is considered to be a mediator of the p53 gene function.⁵⁸ Some studies have indicated that the lack of p21 expression is associated with poor prognosis in patients with squamous cell carcinoma of the anal canal (SCCA). Holm et al.⁵⁹ reported that a lack of p21 expression was associated with reduced OS ($p = 0.013$), whereas Nilsson and colleagues⁶⁰ reported that absence of the same p21 expression was also responsible for an increased LRF rate ($p < 0.05$).

Ajani and colleagues⁵⁵ reported epidermal growth factor receptor (EGFR) expression was observed in 86% of patients with anal cancer, but the study was unable to determine the significant correlation between degree of staining and DFS. The same study's multivariate models suggested that Ki67 (negatively, coefficient: -0.04), nuclear factor kappa B (NF- κ B) (positively, coefficient: 0.07), Sonic Hedgehog (SHH) (positively, coefficient: 0.05), and Gli-1 (positively, coefficient: 0.03) were associated with DFS ($p = 0.005, 0.002, 0.02, \text{ and } 0.02$, respectively). Further investigation into the molecular prognostic factors of anal carcinoma is needed.⁵⁰

TREATMENT OF LOCALIZED SQUAMOUS CELL CARCINOMA

Surgery

As with any disease, treatment decisions in anal cancer are made following a consideration of the risks and benefits. Wide local excision may be considered in a highly select subset of patients of anal cancer patients. This approach should generally be reserved for

small, well-differentiated, superficial lesions confined to the anal margin, not involving the internal sphincter, and without nodal involvement.⁶¹ For lesions that have residual microscopic disease or have close surgical margins less than 1 mm, further local excision, if technically possible, may be pursued, or adjuvant chemoradiation should be considered.⁴⁰

Prior to the mid 1970s, the standard surgical approach to anal cancer was abdominal perineal resection (APR), which required a permanent colostomy following the removal of the rectum, ischio-rectal fat, levator sling, perirectal and superior hemorrhoidal nodes, as well as a wide area of perianal skin, with associated long-term sequelae of sexual and urinary dysfunction. Collectively, long-term DFS results with a surgery alone approach were approximately 50%. A review at the Mayo Clinic of 118 anal cancers treated with APR reported an OS rate of 70% and overall recurrence rate of 40%. Of these, greater than 80% established recurrence sites had either local recurrence alone or some component of such.⁶² Similarly, other surgical series using surgery alone results suggested high rates of regional recurrence (up to 60%) following local excision or APR alone across a variety of stages.⁶³

Definitive Chemoradiotherapy

Given the relatively poor outcomes obtained with APR alone, Nigro et al., from Wayne State University pioneered incorporating concurrent pelvic radiation therapy and chemotherapy (5-FU and MMC) prior to surgical resection, resulting in high rates of pathologic complete response and survival, later verified by other investigators.⁶⁴⁻⁶⁹ This led to significant interest in a *definitive* chemoradiotherapy approach.

Initially, the UK CCCR conducted the ACT I study. In this study, 585 patients with SCC of the anal canal or perianal skin were randomized to receive radiation therapy alone (45 Gy in 20 or 25 fractions), followed by additional radiation dose in patients achieving at least a 50% response (delivering an additional 15 to 25 Gy using either external beam radiation therapy or brachytherapy following a 6-week break) versus a similar radiation approach delivered concurrently with infusional 5-FU (750 mg/m² or 1,000 mg/m² for 5 days given during the first and last weeks of radiation therapy) along with MMC (12 mg/m² delivered on day 1 of treatment). Note that ACT I local failure rates captured several events, including persistence of primary disease following combined modality therapy, the requirement for surgery or colostomy because of treatment failure, as well as ongoing requirement for colostomy at 6 months following the completion of treatment. On the initial report, following a median follow-up of 42 months, the 3-year local failure rate was significantly lower in patients receiving chemoradiotherapy (39% versus 61%; $p < 0.0001$), although at the expense of increased treatment-related morbidity. In particular, hematologic, skin, GI, and genitourinary toxicities were higher with the addition of chemotherapy, with six (2%) treatment-related deaths in the chemoradiation arm versus two (0.7%) for the radiation-alone arm. Although no statistically significant advantage was seen in terms of OS (3-year OS 72% versus 65%; $p = 0.17$), with the addition of chemotherapy, anal cancer-related mortality was significantly improved (28% versus 39%; $p = 0.02$), leading the authors to conclude that patients with SCC of the anal canal could be treated with definitive chemoradiotherapy with surgery reserved for salvage. In a report of long-term follow-up of this trial, no significant differences were seen in terms of long-term morbidity, although an excess in non-anal cancer deaths was seen in the combined modality group in the first 10 years following treatment (cardiovascular, treatment related, pulmonary disease, and second malignancy), but not beyond. LRF rates remained significantly higher in patients treated with radiation therapy alone (25% absolute difference at 12 years), with a corresponding improvement in relapse-free survival (12% absolute at 12 years) through the addition of chemotherapy, with no significant difference reported between the

two groups in terms of late morbidity.^{70,71} Although not statistically significant, an absolute improvement in 12-year survival of 5.6% was seen.

A similar but smaller trial conducted by the EORTC randomized 103 patients with T3-4N0-3 or T1-2N1-3 anal cancer to radiation therapy (45 Gy, with a boost dose of 15 to 20 Gy following a 6-week break, based on disease response), with or without concurrent chemotherapy using infusional 5-FU (750 mg/m² per day, days 1 through 5 and days 29 through 33) with MMC (given on day 1 at 15 mg/m²). Surgery was reserved for patients with less than a partial response. Outcomes from this study revealed that patients treated with concurrent chemotherapy had a higher complete response rate (80% versus 54%) with significant improvement in local-regional control (68 versus 50%), colostomy-free (72% versus 40%) and event-free survival with the addition of chemotherapy at 5 years. Similarly, OS was improved in patients receiving chemotherapy (3 year: 72% versus 65%), although this did not reach statistical significance. Rates of high-grade toxicity were deemed similar between the two groups, although rates of late anal ulceration were higher with the use of concurrent chemotherapy.⁴⁵

The results from these two trials demonstrated that the addition of chemotherapy to definitive radiation therapy significantly improves LRF rates as well as relapse-free and colostomy-free survival rates, although at the expense of increased toxicity.

The Role of Mitomycin in the Combined Modality Therapy Approach of Anal Cancer

Although MMC was delivered concurrently with 5-FU in the aforementioned trials, its necessity was questioned given the association with significant toxicities, including significant myelosuppression, dermatitis, as well as less common side effects of pulmonary fibrosis, hemolytic-uremic syndrome and therapy-related myelodysplastic syndrome. Given this, a randomized trial conducted by the RTOG and ECOG attempted to deintensify therapy by omitting MMC in efforts to preserve oncologic efficacy while eliminating MMC-related toxicity. In this study, patients with anal cancer of any T or N stage were randomized to radiation therapy (45 to 50.4 Gy, with an additional 9 Gy to patients with biopsy-proven persistence of disease 4 to 6 weeks following the completion of initial therapy) with infusional 5-FU (1,000 mg/m² per day on days 1 to 4 and days 29 to 32), with patients randomized to MMC (10 mg/m² days 1 and 29) versus not. Note that in patients with a positive biopsy following the first 4- to 6-week treatment, an additional cycle of cisplatin and 5-FU with radiotherapy was delivered. A second biopsy was later obtained and, if positive for residual tumor, patients proceeded to APR. This study enrolled 310 patients, of which 291 were analyzable. Colostomy-free and disease-free survival rates were significantly higher in patients receiving MMC (71% versus 59% and 73% versus 51%, respectively) with significantly lower colostomy (9% versus 22%) and local failure rates (16% versus 34%). OS was not improved, although as in the previously described randomized studies, was numerically superior (76% versus 67%). Also of note is that all grade 4 and 5 toxicities were considerably higher in patients receiving MMC.⁴⁷ Table 61.3 summarizes the results of randomized phase III clinical trials evaluating combined modality therapy with radiation, 5-FU, and mitomycin versus radiation therapy alone or radiation therapy with 5-FU.

The Role of Cisplatin Concurrent with Radiation Therapy in Anal Cancer

Given the aforementioned toxicities associated with MMC, there has been interest in substituting with a platinum-based chemotherapy when delivered concurrently with radiation therapy. Initial results using this approach from a Cancer and Leukemia Group B (CALGB) pilot study demonstrated that the use of induction 5-FU with cisplatin for advanced anal cancers (T3 to 4, or

node positive) followed by definitive chemoradiotherapy (45 Gy, with or without a 9 Gy boost) with 5-FU and MMC resulted in an 80% complete response rates with 56% and colostomy-free survival.⁷² These and other data led to increasing interest in substituting cisplatin for MMC. The RTOG subsequently conducted a phase III trial (RTOG 98-11), which randomized 644 patients to (1) a standard arm of concurrent chemoradiotherapy (45 to 59 Gy) with continuous infusional 5-FU (1,000 mg/m² per day) and bolus MMC (10 mg/m²) weeks 1 and 5 versus (2) an experimental arm of two cycles of induction continuous 5-FU (1,000 mg/m² per day) and bolus cisplatin (75 mg/m²) alone on weeks 1 and 5, followed by concurrent chemoradiotherapy with two cycles of continuous 5-FU (1,000 mg/m² per day) and bolus cisplatin (75 mg/m²) on weeks 9 and 13. The trial primary endpoint was DFS and secondary endpoint included toxicity analysis. On the initial report, no significant difference was seen in 5-year DFS (60% versus 54%; p = 0.17), OS (75% versus 70%; p = 0.10), or local-regional relapse (25% versus 33%; p = 0.07). However, the 5-year colostomy rate was 10% in the mitomycin group versus 19% in the cisplatin-containing arm (p = 0.02).⁷³ An update of this trial demonstrated a significant improvement in 5-year DFS (68% versus 58%; p = 0.005), OS (78% versus 71%; p = 0.02), and borderline colostomy-free survival (72% versus 65%; p = 0.05) in the MMC-containing arm, albeit at the expense of increased grade 3 and higher hematologic toxicities (61% versus 42%; p < 0.001). However, nonhematologic toxicity rates were equivalent in both arms, with similar rates of late toxicity.⁷⁴ Critics of this study have pointed out that the prolonged the overall treatment duration associated with the use of induction chemotherapy with cisplatin may have allowed for accelerated tumoral repopulation prior to radiation therapy initiation.

A follow-up study from the UK CCCR (the ACT II trial) performed a more direct comparison of the use of cisplatin in conjunction with radiation therapy compared to MMC. In this largest of anal cancer randomized trials, 950 patients with anal or perianal skin cancer were randomized using a 2 × 2 factorial design, with patients randomized to receive infusional 5-FU (1,000 mg/m² per day, on days 1 to 4 and days 29 to 32) with

pelvic radiation therapy (50.4 Gy) plus MMC (12 mg/m² on day 1) versus cisplatin (60 mg/m² on day 1 and 29) with the same 5-FU–radiation regimen. A second randomization was performed following completion of the combined treatment course to no further therapy versus two additional cycles of cisplatin and 5-FU. Grade 3 to 4 acute nonhematologic toxicity rates were similar between the regimens (60% versus 65%; p = 0.17). Not unexpectedly, grade 3 and higher hematologic toxicity rates were greater in the mitomycin group (25% versus 13%; p < 0.001), although no toxic deaths were reported in the trial. In terms of the trial primary endpoint of complete clinical response at 6 months, there was no significant difference between the two groups, and at a median follow-up of 5.1 years, clinical complete response at 26 weeks was 91% in the MMC group compared to 90% in the cisplatin group. Additionally, the 3-year colostomy rate was similar between the two groups (14% mitomycin versus 11% cisplatin). The use of maintenance therapy in this trial showed no obvious benefit, with 3-year recurrence-free survival of 75% in both arms, similar OS rates between the maintenance versus no maintenance groups (85% versus 84%), with 3-year PFS rates of 74% in the maintenance group versus 73% in the nonmaintenance group. The authors concluded that MMC given concurrently with 5-FU and radiation therapy should remain the standard in the treatment of anal cancer, given the following: (1) the high grade hematologic toxicity seen with MMC did not significantly increase sepsis rates; (2) the MMC course was delivered over approximately 10 minutes compared to two courses of either all day or overnight intravenous (IV) hydration with cisplatin, with similar efficacy and overall toxicities between the regimens; (3) fewer chemotherapy cycles were required; (4) there was requirement for fewer nonchemotherapy drugs; (5) there was lesser expense; and (6) there was no risk of neuropathy.⁷⁵

Another phase III trial conducted by the French Federation Nationale des Centres de Lutte Contre La Cancer ACCORD (the ACCORD-03 trial) randomized patients with stage II to III anal cancer to one of four treatment arms: (1) neoadjuvant 5-FU + cisplatin alone followed by 5-FU cisplatin radiation therapy (45 Gy) with a radiation therapy boost (15 Gy) using either external

beam or brachytherapy techniques; (2) same as the first arm, except utilizing a higher dose radiation boost (20 to 25 Gy); (3) same as the first arm, but no neoadjuvant chemotherapy; and (4) same as the second arm, but no neoadjuvant chemotherapy. Of note is that a 3-week break was mandated following the completion of the initial 45 Gy, prior to boost treatments. Following a median 50-month follow-up, there was no significant difference in 5-year colostomy-free survival rates (70% to 82%). Similarly, no significant differences were seen between the arms in terms of LRF, cause-specific survival, and OS. The most intensified treatment arm of induction chemotherapy with high-dose radiation boost demonstrated a numerically improved local control (88% versus 72% to 83% on the additional arms). The trial authors indicated that induction chemotherapy does not improve outcomes, with the role of radiation dose escalation in this disease remaining uncertain, but felt that the combination of induction chemotherapy and radiation dose escalation should be explored further.⁷⁶ The results of randomized trials evaluating cisplatin are shown in Table 61.4.

Novel Biologic Radiosensitizing Agents

To date, no biologic agent has been granted U.S. Food and Drug Administration (FDA) approval as an effective radiosensitizer in anal cancer. Early reports have described outcomes of combined treatment modality with EGFR inhibitors, with varying degrees of response and toxicity.^{79,80} These and other studies are warranted to assess the role of treatment intensification, particularly in more advanced disease where outcomes are less favorable.

Traditional Radiation and Intensity Modulated Radiation Therapy

The use of combined modality therapy in the definitive treatment of anal cancer results in significant acute as well as late toxicities. All the previously mentioned randomized trials used radiation therapy planned and delivered using either conventional 2-dimensional or 3-dimensional radiation planning techniques. This approach frequently entails treating large volumes of nontarget tissues (bowel, bladder, bone, genitalia), leading to the aforementioned morbidities. Although 3-dimensional planning results in potentially improved normal tissue sparing through the use of axial CT images to define the target volume as well as normal tissue structures, results remain suboptimal. Intensity-modulated radiation therapy is an advanced form of 3-dimensional conformal radiation therapy that implements multiple beams using a non-uniform dose delivery. This can be accomplished in a variety of ways, all of which entail the use of collimating leaves that sweep across the beam path during treatment delivery. Through inverse computer planning techniques, the radiation dose can be more tightly conformed to target tissues with dose reductions to adjacent, nontarget organs. With this technique, there is a significant potential to reduce both acute and long-term morbidity associated with anal cancer treatments. Multiple institutional studies have indicated that, compared to patients treated with non-intensity-modulated radiation therapy (IMRT) techniques, a significant reduction of treatment-related toxicity can be accomplished.^{81,82} Additionally, with corresponding reductions in acute toxicity, there may be a reduction in the need for treatment breaks, with the potential to further influence disease-related outcomes.⁸³ A prospective trial evaluating IMRT for anal cancer was conducted through the RTOG (0529 study). In this phase II trial, patients received concurrent 5-FU with MMC. Radiation therapy was delivered through a *dose-painting* technique, whereby differing target volumes received differing doses of radiation therapy during any one treatment as defined by the study. The primary endpoint of this study included an assessment of grade 2 or higher GI and genitourinary toxicities as compared to the previously described RTOG 98-11 trial (MMC-containing arm). In 52 analyzable patients (out of 63 accrued), rates of grade 3 or higher dermatologic toxicity

were improved in the IMRT study (20% versus 47%; $p < 0.001$) as were rates of grade 3 or higher GI and genitourinary toxicity (22% versus 36%; $p = 0.014$). Additionally, median radiation duration was 42.5 days in the IMRT study compared to 49 days in 98-11, with similar 2-year disease-related outcomes when compared to RTOG 98-11.^{84,85} An important caveat to this trial was that a central reviewer performed pretreatment quality assurance on all patients. Of initially submitted plans, 81% required planning revisions, with 46% of plans requiring two or more revisions. Although this trial did not formally meet its primary endpoints in reduction and acute toxicities, it does suggest that the use of IMRT can significantly reduce high-grade GI, genitourinary, and skin toxicities without compromising treatment-related outcomes, and that there is also a significant learning curve for the use of IMRT in the treatment of anal cancer. Figure 61.5 demonstrates an example of an anal cancer plan implementing IMRT.

Follow-Up Management

Given that SCC of the anus can regress slowly following treatment completion (up to 12 months), it is generally recommended that patients who have regressive disease do not undergo repeat biopsies given this may lead to nonhealing ulceration and chronic wound infection in previously irradiated tissues.^{45,86} Exemplifying this phenomena, in a preliminary report from the ACT II trial, 72% of patients who had not achieved a clinical complete response at 11 weeks ultimately achieved such at 26 weeks from treatment initiation,⁸⁷ indicating that premature biopsy following definitive chemoradiotherapy may result in the aforementioned complications as well as premature *salvage* surgery in some cases. Of the 265 patients in the ACT II trial not in complete response at week 11, only 83 ultimately had progression/persistent disease.

Approximately 20% to 25% of patients with SCC treated by chemoradiation will either fail to completely respond or relapse within the first 3 years after treatment. Posttreatment evaluation is critical to assess the effectiveness of therapy and to detect a persistent or recurrent tumor.⁸⁶ The first evaluation typically is between 8 to 12 weeks after the completion of chemoradiation. The physical examination should include a visual inspection, a digital rectal exam, an anoscopy, and palpation of the inguinal nodal regions. Ongoing clinical evaluation typically occurs every 3 to 6 months for the first 2 years, then every 6 to 12 months until 5 years following completion of chemoradiation. It may be appropriate to conduct less intense follow-ups following 3 years, given that only 7% of relapses occur beyond this time point.⁸⁸ Lesions persisting beyond 3 months following treatment are more concerning for residual disease; however, as stated previously, it is important to assess changes over time. If a tumor continues to shrink, then close clinical surveillance is advised. Chronically persistent or recurrent tumors should be biopsied for confirmation of SCC.⁶¹ Discretion regarding the size and depth of biopsies is needed because extensive biopsies may result in nonhealing ulcers and chronic wound infection.⁴⁵ As an adjunct to physical examination, imaging studies for posttreatment surveillance should be considered.⁶¹ Current NCCN guidelines recommend a CT scan of the chest, abdomen, and pelvis annually for 3 years for patients who had T3 or T4 disease or positive inguinal nodes.

Treatment for HIV Population

Unfortunately, the majority of pivotal phase III trials did not allow the inclusion of HIV-positive patients. There are studies suggesting that anal cancer patients with HIV comorbidities have comparable rates of response to HIV-negative patients while being treated with chemoradiation.⁸⁹⁻⁹¹ Earlier studies suggested that there was a potential for HIV-positive patients to experience higher toxicities and inferior treatment compliance, which could ultimately alter their outcomes.^{92,93} Most studies addressing the application

Note relative organ sparing and *bending* of isodose curves around normal structures including anteriorly based (genitalia) and femora bilaterally while still encompassing the primary target volume of his gross tumor (*red*) as well as local-regional lymph nodes basins (perirectal and inguinal). Note that *colored lines* (isodose curves) represent varying radiation doses.

and outcomes of standard combined regimens for the treatment of anal cancer with HIV-positive patients describe small sample sizes. There are several studies where investigators endeavored to describe the outcomes of treatment modalities for anal carcinomas based on CD4 cell count.^{94,95} According to Hoffman et al.,⁹⁴ patients with CD4 count $\geq 200/\text{mm}^3$ tolerated combined therapy (5-FU/MMC/radiation) better (decreased likelihood of toxicity) compared with patients who had CD4 counts $< 200/\text{mm}^3$. In the Cook County Hospital AIDS Malignancy Project (CHAMP) study, median survival in the HIV-positive versus HIV-negative patients was 34 versus 39 months ($p > 0.5$). In the HIV-negative population, 22% survived 120 months, whereas no HIV patient survived over 90 months, and time to local recurrence was 20 months shorter in the HIV-positive arm ($p < 0.5$), with the authors speculating this may imply more aggressive disease. OS based on CD4 count did not differ.¹³

Preliminary safety and efficacy results were presented on the administration of two doses of cetuximab, cisplatin, 5-FU and with radiation therapy (45 to 54 Gy) in immunocompetent (ECOG 3205, $n = 28$) and HIV-positive (AMC045, $n = 45$) patients with non-metastatic (stage I to III) squamous cell carcinoma of anal canal.⁹⁶ These results showed that the PFS and OS rates in the subsequent 2 years were 80% and 89% for HIV-positive patients with anal cancer, compared to 92% and 93%, respectively for HIV-negative patients. The authors concluded that combined cetuximab, cisplatin, 5FU and radiation combination therapy in HIV positive patients with anal cancer yielded favorable outcomes based on feasibility, safety and efficacy. Further data on these two companion studies are indicated and evaluation within a randomized clinical trial would be required to determine whether patients with anal cancer benefit from an EGFR-targeted therapeutic agent.

HAART is important for bolstering CD4 cell counts in patients with HIV. To analyze the impact of HAART on patients with anal cancer receiving combined modality therapy (CMT), Place and colleagues⁹⁵ completed a small study in which patients were divided into two groups: one group received CMT before HAART implementation, and the other group received CMT following HAART therapy. The authors concluded that the patients who received CMT after the advent of HAART had better outcomes, although it was speculated interpretation could be hampered by the fact HAART alone might have altered the immune status of the patients.⁹⁵ In a French study, clinical outcomes of anal cancer patients with HIV treated with HAART and chemoradiation were similar to immunocompetent (HIV

negative) controls.⁹⁷ More recently, however, a single institution French study⁹⁸ reported significantly poorer outcomes for their HIV-positive compared to HIV-negative patients. Local control was achieved in 50% versus 77%, with corresponding 5-year OS rates of 30% versus 84% and DFS rates of 37% versus 75%, respectively. In addition, HIV-infected patients were more likely to be younger and male, although no significant differences were seen in terms of stage or other tumor characteristics. These investigators postulated that the worsened outcomes may have resulted from a higher frequency of advanced disease in their population relative to other studies and a reflection of lack of routine and local screening programs. However, a follow-up study at Case Western University showed that both HIV-positive and HIV-negative patients treated with HAART had comparable treatment efficacy and toxicity rates.⁹⁹ Finally, a pooled analysis of 121 patients with anal cancer treated in the HAART era revealed similar complete response and OS rates among HIV-positive and HIV-negative patients, although HIV-positive patients were much more likely to experience local failure (5-year 62% versus 13%; $p = 0.008$) along with increased acute dermatologic and hematologic toxicities with treatment.¹⁰⁰

There is a general concern that cancer patients receiving chemotherapy are predisposed to develop immunosuppression, particularly in the setting of an immunodeficiency disease such as HIV, thus complicating the treatment choice and follow-up plan. There is also a potentially greater chance of experiencing adverse treatment reactions that can hinder treatment compliance. Although it is usually not necessary to alter standard management recommendations, HIV-infected patients, especially those with a CD4 count less than $200/\mu\text{L}$, should be monitored for an increased risk of toxicity when treated with chemoradiation. Given the previously described ACT I and EORTC trial results, chemotherapy omission is generally not recommended. Thus, factors including pretreatment CD4 cell count, HAART compliance, posttreatment CD4 cell count, and performance status, must come into account in order to formulate a favorable combined treatment modality for anal cancer patients on a personalized, case-by-case basis.

Salvage Therapy for Local Recurrence

APR is recommended for patients who have chronically persistent disease or who develop recurrence. Restaging is performed to evaluate the extent of the disease and determine the presence of extrapelvic metastases. Curative surgery must attain negative margins for oncologic success, and tumor invasion into adjacent organs warrants en bloc resection. Invasion of local structures, including the vagina or prostate, should be approached with an intent of resecting with negative margins. This may involve a multivisceral resection. In instances where there may be close or involved margins at resection, the use of intraoperative radiotherapy or brachytherapy may enhance local control rates. In highly selected cases, there may be a role for low-dose reirradiation with concurrent chemotherapy followed by resection and intraoperative radiotherapy. The majority of published series describing outcomes with salvage surgery have small patient numbers given the relative rarity of such. Five-year survival following resection generally ranges between 30% to 70%, with DFS rates ranging from 30% to 40% (Table 61.5). The most important prognostic factor of survival after resection is margin status, and patients with negative margins (R0) have up to a 75% 5-year OS.¹⁰¹ Further predictors of a poor OS outcome following surgery include inguinal lymph node involvement, tumor size greater than 5 cm, adjacent organ involvement, male gender, and comorbidities.^{102,103} In one of the largest series describing salvage surgery in anal cancer, Correa et al.¹⁰⁴ proposed a scoring system predicting postoperative survival. The three factors included were lymph

TABLE 61.5

Results of Salvage Surgery for Residual or Recurrent Anal Cancer

Study	Patient Number	Negative Margin After Surgery (R0)	5-Year Survival Based on Margin Status	Overall 5-Year Survival
Akbari et al., 2004 ¹⁰²	62	85%	R0 = 38% R½ = 0%	33%
Nilsson et al., 2002 ¹⁰⁵	35	91%	NS	52%
Ghouti et al., 2005 ¹⁰⁶	36	NS	NS	69.4% (DFS, 31.1%)
Renehan et al., 2005 ¹⁰⁷	73	75%	R0 = 61.4% R½ = 0%	40%
Schiller et al., 2007 ¹⁰³	40	83%	NS	39% (DFS, 30%)
Ferenschild et al., 2005 ¹⁰⁹	18	78%	NS	30%
Sunesen et al., 2009 ¹⁰¹	45	78%	R0 = 75% R1 = 40% R2 = 0%	61%
Eeson et al., 2011 ¹¹⁰	51	63%	R0 = 42% R½ = 0%	29%
Lefevre et al., 2012 ¹¹¹	105	82%	R0 = 69% R1 = 0%	61%

R0, clear margin; R1, microscopic positive margin; R2, grossly positive margin; NS, not stated.

node involvement, involved surgical margins, and perineural and/or lymphovascular invasion.¹⁰⁴ Patients who had none of these factors (i.e., a score of 0), had an estimated 5-year survival of 55%; however, those with scores of 1 to 3 did much worse, with 5-year survival of 0.03% in patients with all of the factors. The utility of such a system is to define a subgroup that would potentially benefit from additional postoperative treatments. The majority of reported series describing salvage surgery indicate that persistence of disease (as opposed to recurrence) following combined modality therapy was the primary reason for such an approach. In patients undergoing salvage surgery, even with R0 resection, patients with disease persistence tend to have worse outcomes, with 5-year overall survival rates ranging from 31% to 33% as compared to 51% to 82% for truly recurrent patients.^{102,105} It is been hypothesized that persistent tumors may harbor a more aggressive tumor biology resistant to chemoradiotherapy, leading to worse outcomes. Overall, length of time to recurrence following resection varies from 1 to 50 months.^{101,103,106,107}

Salvage resection is associated with significant morbidity in up to 72% of patients, including side effects of delayed perineal wound healing, pelvic abscesses, perineal wound hernia, urinary retention, as well as the development of impotence. Perineal wound healing difficulties are a result of both the large soft tissue defect created in fully excising these tumors as well as potentially impacted by prior radiation therapy. Closure of the wound by primary intention produces suboptimal results if not combined with flap placement. In one series of 22 patients undergoing salvage APR with primary closure, 59% experience perineal wound break down, with 1 requiring reconstructive operation.¹⁰⁷ Commonly used tissue flaps include an omental pedicle flap, a gracilis muscle flap, and the vertical rectus abdominis myocutaneous flap (VRAM). In one series of 95 patients undergoing salvage APR, patients undergoing an omental pedicle flap, as compared to a VRAM flap, had more perineal wound complications and slower healing.¹⁰⁸ In another smaller series, the perineal wound breakdown rate with the use of omental flap reconstruction was 36% versus 0% with a VRAM flap following APR.¹¹⁰ Finally, a series

of 48 patients who underwent salvage APR reported no delays in wound healing or infectious complications when a VRAM flap was used.¹⁰¹

Management of Metastatic Disease

Randomized studies have demonstrated that patients treated with chemoradiation can develop metastatic disease in 10% to 17% of cases.^{43,70} Currently, systemic chemotherapy is the treatment of choice for metastatic anal cancer. However, there is little published data in the setting of metastatic disease. Much of the treatment has been extrapolated from more common squamous cell cancers such as head and neck cancer, cervical cancer, etc. A 5-FU/cisplatin combination is recommended by the NCCN⁴⁰ guidelines as the first-line regimen to treat metastatic anal SCC.

There are a few small studies that report the benefit of administration of the previous mentioned regimen in patients with metastatic SCCA.^{86,112-115} Most notably, according to Faivre et al.,¹¹² survival at 1 and 5 years were 62.2% and 32.2%, respectively, whereas the median survival was 34.5 months.

MMC and 5-FU may also be considered for first-line therapy¹¹⁶ for metastatic SCCA. One study showed that patients treated with this regimen ultimately achieved better response that included tumor size shrinkage, pain management, and performance improvement. There are additional combination chemotherapy trials and single agent case reports available that are described briefly in Table 61.6.¹¹⁷

Cetuximab has shown favorable outcomes for the treatment of SCC of the head and neck while delivered concurrently with radiation therapy.¹²⁵ However, the data supporting the administration of cetuximab in metastatic SCCA is scant. According to a few small studies and case reports, the maximum clinical response achieved was a partial response, with varying ranges of PFS with cetuximab/irinotecan combination therapy.¹²⁶⁻¹²⁸ Due to the very small sample sizes of these studies, a further evaluation is warranted.

TABLE 61.6

Like other GI cancers, the liver is the primary site of metastasis from anal cancer. Data on the resection of an isolated hepatic lesion are sparse, and currently, a definitive surgical treatment protocol remains largely undefined in the metastatic setting. That said, surgical resection of metastatic disease can be considered when appropriate, based on the extent of disease and performance status. According to Eng et al.,¹²¹ the median PFS and OS of 33 out of 77 patients with metastatic anal SCCA who received curative surgical treatment for their metastatic disease were 16 (95% CI, 9.2 to 22.8) and 53 months (95% CI, 28.3 to 77.6), respectively. Previously, a multicenter study¹²⁹ comprising of 52 patients also suggested that a subset of patients might benefit from surgical resection. According to the study, among 27 metastatic squamous cell anal carcinoma patients pretreated with systemic therapy, the median PFS and OS were 9.6 and 22.3 months, respectively, although definitive selection criteria for surgical resection were lacking.

Outcome, benefit, and toxicity analysis on chemoradiation for metastatic anal cancer is limited. A small study¹³⁰ (n = 6) from the M.D. Anderson Cancer Center of patients with para-aortic nodal involvement was reported. In this study, all the patients were treated with IMRT with concurrent infusional 5-FU and cisplatin. The results showed that 3-year actuarial local–regional control, distant control, and survival rates were 100%, 56%, and 63%, respectively. In another study, a short course of chemoradiation comprised of 30 Gy with concurrent 5-FU demonstrated good local–regional control (73% at the median follow-up of 16 months) in elderly patients (median age 81 years).¹³¹ Combined chemoradiation may also be used to palliate symptoms related to metastatic disease.

The International Rare Cancer Initiative (IRCI) in collaboration with the NCI has expressed interest specifically focusing on establishing guidelines for metastatic anal cancer squamous carcinoma patients, including diagnostic imaging, staging, surveillance, and survivorship. The first initiative is an international collaboration with the United Kingdom, EORTC, and ECOG/ACRIN on a randomized phase II trial of 5-FU/cisplatin versus carboplatin/paclitaxel in treatment-naïve patients (InterAACT).

TREATMENT OF OTHER SITES AND PATHOLOGIES

Squamous Cell Carcinoma of the Anal Margin

The definition of anal margin tumors has varied over time, ranging from perianal skin to the distal aspect of the anal canal.

A generally accepted, contemporary definition includes the area extending from the anal verge radially 5 cm outward on the perianal skin. The onset of this disease is frequently seen in the 7th and 8th decades of life, with a slight female predominance.^{116,132,133} The majority of these tumors are well differentiated, indicating a slow growing nature with the development of distant metastases rare.^{116,134,135} The primary drainage is to the inguinal region and regional nodal metastases directly related to tumoral size. Once series¹³⁶ describes that tumors less than 2 cm rarely exhibit lymph node metastases, 2 to 5 cm tumors associated with an approximately 23% node positive rate, and in tumors larger than 5 cm, rates as high as 67%. Therefore, it is important that these tumors be approached on an individual basis based on size, location, and histologic characteristics. Tumors whose epicenter is distal to the anal verge may be managed as skin tumors. Potential treatment options for these patients include local excision with or without adjuvant radiation therapy, or radiation with or without chemotherapy. Treatment considerations in these patients must take into account expected morbidity with such approaches. For smaller tumors, wide local excision with a 1-cm margin is often sufficient. However, surgery for larger tumors may require more aggressive removal, which may entail APR; combined modality therapy may be an appropriate alternative in such cases, particularly where the risk of lymph node involvement is high. Therefore, surgery is often reserved for tumors <2 cm in greatest dimension without adverse histologic features and no involvement of the anal sphincter. APR should generally be reserved for patients with recurrent disease following radiation/chemoradiation or recurrence not amenable to local excision. Chapet and colleagues¹³⁷ reviewed an experience of 26 patients with tumors of the perianal skin, 5 with involvement of the anal canal. Most were ≤5 cm in diameter. Fourteen received definitive radiation therapy, with or without chemotherapy, and 12 received radiation therapy following initial local excision. Actuarial local control rate was 61%, and with salvage surgical treatment, this increased to 81%, with a 5-year cause-specific survival of 88%. Khanfir et al.¹³⁸ reported similar results in a series of 45 patients. Twenty-nine patients underwent local excision prior to radiation therapy. Five-year local–regional control was 78% with 5-year DFS of 86%. Balmucki et al.¹³⁹ updated at University of Florida experience with definitive radiotherapy and chemoradiotherapy in 26 patients with SCC of the perianal skin. Two patients developed local recurrence and two developed regional nodal recurrence, resulting in a 10-year cause-specific survival of 92%. Of note, two patients who had clinically node-negative disease who did not receive prophylactic inguinal nodal radiation developed inguinal recurrences.

Anal Canal Adenocarcinoma

Primary adenocarcinoma of the anal canal is an uncommon tumor. In many situations, this will represent growth of a distal rectal adenocarcinoma into the anal canal and is managed as such. In some instances, this disease is believed to arise from glandular epithelium in the anal canal, accounting for less than 5% of all anal malignancies.¹⁴⁰ Occasionally, adenocarcinoma may occur in patients with ulcerative colitis or Crohn's disease who have ileal pouch–anal anastomosis.^{141–143} A study from the Rare Cancer Network registry of 82 patients diagnosed with anal adenocarcinoma was analyzed based on the treatment approach. The actuarial local–regional relapse rate at 5 years was 37%, 36%, and 20%, respectively, in the radiation/surgery, combined chemoradiation therapy alone, and APR alone groups. The 5-year OS rate was 29%, 58%, and 21% and 5-year DFS rate 25%, 54%, and 22%, respectively. A multivariate analysis revealed four independent prognostic factors for survival: T stage, N stage, histologic grade, and treatment modality (chemoradiotherapy). The authors concluded that they observed better survival rates after combined chemoradiotherapy and recommended using APR only for salvage treatment.¹⁴⁴ In contrast, a Surveillance, Epidemiology, and End Results (SEER) study evaluated 165 patients with nonmetastatic adenocarcinoma of the anal canal. Of these, 30 patients were treated with an APR only, 42 patients with an APR and radiation, and 93 patients with radiation alone. The 5-year survival for APR only, APR and radiation, and radiation alone was 58%, 50%, and 30%, respectively ($p = 0.04$). A multivariate analysis confirmed factors accounting for the survival differences included age, nodal stage, and treatment groups. The authors concluded definitive surgical treatment in the form of an APR with or without radiation is associated with improved survival in these patients.¹⁴⁵ An institutional report from the M. D. Anderson Cancer Center analyzed 16 patients with anal adenocarcinoma and compared outcomes with definitive chemoradiotherapy to similarly treated patients with squamous cell tumors.¹⁴⁶ At 5-years, local failure rate was 54% in the adenocarcinoma group compared to 18% for patients with SCC, with corresponding 5-year DFS of 19% versus 77%, respectively, and OS rates of 64% versus 85%. Given this, patients with primary anal adenocarcinoma are generally treated as if they had rectal adenocarcinomas of similar stage, with surgery remaining as a cornerstone therapy and neoadjuvant radiation therapy or combined modality therapy generally implemented in patients with high-risk features (T3 or T4 and/or nodal involvement).

Anal Paget disease is an intraepithelial adenocarcinoma arising from the dermal apocrine sweat glands, most commonly found in females and in older patients.³⁴ Although progression from perianal Paget disease to invasive disease is seen in approximately 5% of cases, invasive cancers have been reported up to 40% of patients with untreated Paget disease. Association with tubo-ovarian adenocarcinoma was seen in 7% to 24% and GI cancers in 12% to 14%

of cases.³⁴ Therefore, appropriate imaging and fiber-optic endoscopy studies are recommended to rule out synchronous underlying malignancies.

Melanoma of the Anorectal Region

Anorectal melanoma is a rare disease that accounts for approximately 1% of all malignant melanomas and 0.5% of tumors of anorectal area.^{147–149} Symptoms are rather nondescript, with bleeding manifesting as the most common complaint.¹⁵⁰ The gross appearance varies from a small, pigmented lesion to an ulcerated mass. Anal canal melanomas are usually pigmented lesions, but can be amelanotic in as many as 29% of cases.¹⁵¹ A SEER database review reported a 5-year OS of 2.5%,¹⁵² although some series report up to a 20% survival.^{149,150,153} Surgery is the cornerstone of treatment with debate regarding the optimal approach. Traditionally, surgeons adopted a more radical approach utilizing APR with a radical lymph node dissection. However, this approach was associated with significant morbidity without improving OS. Kiran et al.¹⁵⁴ reviewed 109 patients with anorectal melanoma from the SEER database between 1982 and 2002 and reported no significant difference between patients treated by APR or local resection. A retrospective review of 251 patients from the Swedish National Cancer Registry between 1960 and 1999 demonstrated similar findings.¹⁵⁵ A recent systematic review comparing APR to wide local excision in anal melanoma patients reported similar median survivals regardless of treatment approach (21 months for APR, $N = 369$; 20 months for local excision, $N = 324$). Similarly, the treatment approach did not significantly impact 5-year survival (14% for APRs, 15% for local excision).¹⁵⁶

There are some centers that advocate more aggressive treatment for localized disease, arguing for better oncologic outcomes in select subsets. In an older Memorial Sloan Kettering experience, factors associated with long-term survival following APR included female gender, negative lymph nodes, and tumor size less than 2.5 cm, concluding APR may be considered in the subset of patients with these features.¹⁵⁰ A Japanese study that included 79 patients with anorectal melanoma reported 3- and 5-year survival rates of 34.8% and 28.8%, respectively (median survival 22 months), for patients treated by APR.¹⁵⁷ Therefore, the authors of that study recommended local excision for patients with stage 0 melanoma, whereas those with stage I cancers or T1 tumors should undergo an APR with lymph node dissection. Ballo et al.¹⁵⁸ reported on 23 patients treated at the M. D. Anderson Cancer Center with sphincter sparing excision and adjuvant radiation therapy using a hypofractionated regimen of 30 Gy delivered in five fractions. Nine patients received systemic therapy. Five-year actuarial overall, disease-free, distant metastases-free, local, and regional nodal control rates were 31%, 37%, 35%, 74%, and 84%, respectively, comparing favorably to varying reports using local excision alone.

Section 4 Cancers of the Genitourinary System

62 Molecular Biology of Kidney Cancer

W. Marston Linehan and Laura S. Schmidt

INTRODUCTION

Kidney cancer or renal cell carcinoma (RCC) affects more than 271,000 people annually worldwide, resulting in 116,000 deaths each year.¹ A variety of risk factors, including obesity, hypertension, tobacco smoking, and certain occupational exposures, have been shown to increase one's risk for developing RCC. Our current understanding of the molecular genetics of kidney cancer has come from studies of families with an inherited predisposition to develop renal tumors. Individuals with a family history of RCC have a 2.5-fold greater chance for developing renal cancer during their lifetimes² and comprise about 4% of all RCCs.

Kidney cancer is not a single disease, but rather is classified into tumor subtypes based on histology.³ Over the past 2 decades, studies of families with inherited renal carcinoma enabled the identification of five inherited renal cancer syndromes and their predisposing genes (Table 62.1), which implicate diverse biologic pathways in renal cancer tumorigenesis.⁴ The von Hippel-Lindau (*VHL*) tumor suppressor gene was discovered in 1993.⁵ Subsequently, activating mutations were identified in the *MET* protooncogene in patients with hereditary papillary renal carcinoma (HPRC).⁶ More recently, germ-line mutations in the gene for Krebs cycle enzyme fumarate hydratase (*FH*), responsible for hereditary leiomyomatosis and renal cell carcinoma (HLRCC),⁷ and in *FLCN*, the gene for Birt-Hogg-Dubé (BHD) syndrome, were identified.⁸ Germ-line mutations in the genes encoding subunits B, C, and D of another Krebs cycle enzyme, succinate dehydrogenase (*SDHB/SDHC/SDHD*), have been found in patients with familial renal cancer.⁹⁻¹¹ Discovery of the genes for the inherited forms of renal cancer has enabled the development of diagnostic genetic tests for presymptomatic diagnosis and improved prognosis for at-risk individuals.

VON HIPPEL-LINDAU DISEASE

Von Hippel-Lindau (*VHL*) disease is an autosomal-dominant inherited multisystem neoplastic disorder that is characterized by clear cell renal tumors, retinal angiomas, central nervous system hemangioblastomas, tumors of the adrenal gland (pheochromocytoma), endolymphatic sac and pancreatic islet cell, and cysts in the pancreas and kidney. *VHL* occurs in about 1 in 36,000 and develops during the 2nd to 4th decades of life with nearly 70% penetrance by age 60. Bilateral, multifocal renal tumors with clear cell histology develop in 25% to 45% of *VHL* patients¹² that can have metastatic potential when they reach 3 cm.

Genetics of *VHL*

Loss of heterozygosity (LOH) on chromosome 3p in clear cell renal tumors suggested the location of a predisposing gene for RCC.¹³ Positional cloning in *VHL* kindreds defined the disease locus to

chromosome 3p25-26, leading to the cloning of the *VHL* gene in 1993.⁵ *VHL* is a tumor suppressor gene in which both copies of *VHL* must be inactivated for tumor initiation. Germ-line *VHL* mutations that predispose individuals to *VHL* encompass the entire mutation spectrum, including large deletions, protein-truncating mutations, and missense mutations that exchange the amino acid in the *VHL* protein. Over 700 different *VHL* mutations have been identified in more than 945 *VHL* families worldwide. Mutations are located throughout the entire gene with the exception of the first 35 residues in the acidic domain.¹² With the development of new methods for detection of deletions, *VHL* mutation detection rates are approaching 100%.^{14,15} *VHL* subclasses based on the predisposition to develop pheochromocytomas and a high or low risk of RCC have been established with clear genotype-phenotype associations emerging.¹⁶

Gene Mutated in Renal Cancer Families with Chromosome 3p Translocations

In 1979, Cohen et al.¹⁷ described a family with a constitutional t(3;8)(p14;q24) balanced translocation that cosegregated with bilateral multifocal clear cell renal tumors. Loss of the derivative chromosome carrying the 3p segment and different somatic mutations in the remaining copy of *VHL* were identified in the tumors from this translocation family. Based on these data, Schmidt et al.¹⁸ proposed a three-step tumorigenesis model in 3p translocation families: (1) inheritance of the constitutional translocation, (2) loss of the derivative chromosome bearing 3p25, and (3) mutation of the remaining copy of *VHL*, resulting in inactivation of both copies of *VHL* and predisposing individuals to clear cell RCC. A number of chromosome 3 translocation families have been described.^{19,20} Loss of the derivative chromosome concomitant with the somatic mutation of the remaining copy of *VHL* in these families provides strong evidence for the three-step tumorigenesis model and implicates *VHL* loss in clear cell RCC that develops in chromosome 3 translocation kindreds.

Gene for Sporadic Clear Cell Kidney Cancer

Somatic mutation of the *VHL* gene with associated loss of the wild-type allele is found in a high percentage of tumors from patients with clear cell kidney cancer.²¹ Nickerson et al.²² recently identified mutation or methylation of the *VHL* gene in 92% of clear cell kidney cancers. The *VHL* gene mutation is not found in papillary, chromophobe, collecting duct, medullary, or other types of kidney cancer.

Function of the *VHL* Protein

The most well-understood function of the *VHL* protein pVHL is the substrate recognition site for the hypoxia-inducible factor

TABLE 62.1

Hereditary Renal Cancer Syndromes

Syndrome	Chromosome Location	Predisposing Gene	Histology	Frequency of Gene Mutations	
				Germ Line	Sporadic RCC
Von Hippel-Lindau (VHL) disease	3p25	<i>VHL</i>	Clear cell	100% ¹⁴	92% ²²
Hereditary papillary renal carcinoma type 1 (HPRC)	7q31	<i>MET</i>	Type 1 papillary	100% ^{6,41,42}	13% ⁴⁵
Birt-Hogg-Dubé syndrome (BHD)	17p11.2	<i>FLCN</i>	Chromophobe, hybrid	90% ⁶⁵	11% ⁷⁶
Hereditary leiomyomatosis and renal cell carcinoma (HLRCC)	1q42–43	<i>FH</i>	Type 2 papillary	93% ¹⁰⁵	TBD
Succinate dehydrogenase (SDH)-associated familial renal cancer	1p35–36 1q23.3 11q23	<i>SDHB</i> <i>SDHC</i> <i>SDHD</i>	Clear cell, chromophobe, oncocytic neoplasm	TBD	TBD
Tuberous sclerosis complex (TSC)	9q34 16p13.3	<i>TSC1</i> <i>TSC2</i>	Angiomyolipoma, all histologies	80%–90%	TBD

TBD, to be determined.

(HIF)- α family of transcription factors targeting them for ubiquitin-mediated proteasomal degradation (Fig. 62.1).¹⁶ pVHL binds through its α domain to elongin C and forms an E3 ubiquitin ligase complex with elongin B, cullin-2, and Rbx-1. Under normal oxygen conditions, HIF- α becomes hydroxylated on critical prolines by a family of HIF prolyl hydroxylases (PHD) that require α -ketoglutarate, molecular oxygen, ascorbic acid, and iron as cofactors. pVHL then binds to hydroxylated HIF- α through its β domain, targeting HIF- α for ubiquitylation by the E3 ligase complex. Under hypoxic conditions when PHDs are unable to function or when pVHL is mutated—thereby altering its binding to HIF- α or elongin C—HIF- α cannot be recognized by pVHL. HIF- α accumulates and transcriptionally upregulates a number of genes important in blood vessel development (*EPO*, *VEGF*), cell proliferation (*PDGF β* , *TGF α*), and glucose metabolism

(*GLUT-1*).¹⁶ HIF- α -dependent upregulation of target genes involved in neovascularization provides an explanation for the increased vascularity of central nervous system (CNS) hemangioblastomas and clear cell renal tumors in VHL. Germ-line *VHL* mutations frequently occur in the pVHL binding domains for HIF- α and elongin C.²³ HIF-2 α (rather than HIF-1 α) stabilization appears to be critical for renal tumor development.^{24,25} Additional HIF-independent functions for pVHL have been reported,^{12,16,26} including an increase of p53 activity through the suppression of MDM2-mediated ubiquitination and nuclear export,²⁷ modulation of nuclear factor κ B (NF- κ B) through casein kinase 2 binding and inhibitory phosphorylation of NF- κ B agonist CARD9,²⁸ microtubule stabilization,²⁹ maintenance of primary cilium,³⁰ and extracellular matrix formation affecting cell-cell adhesion.^{31,32}

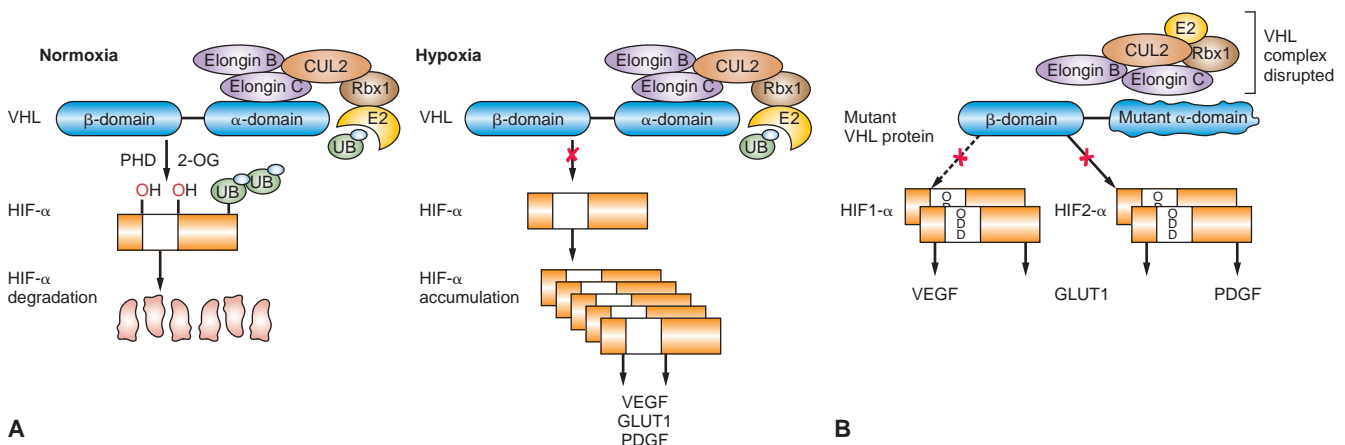

Figure 62.1 The von Hippel-Lindau (VHL) E3 ubiquitin ligase complex targets hypoxia-inducible factor (HIF)- α for ubiquitin-mediated degradation. **(A)** Under normal oxygen conditions, HIF- α is hydroxylated on critical prolines by HIF prolyl hydroxylase (PHD), requiring molecular oxygen, α -ketoglutarate (2-OG), and iron as cosubstrates. The VHL protein (pVHL) can then recognize and bind hydroxylated HIF- α , enabling ubiquitylation by the VHL E3 ligase complex and degradation by the proteasome. Under hypoxic conditions, PHD is unable to function properly, pVHL cannot recognize HIF- α , and HIF- α accumulates, leading to the upregulation of HIF-target genes (*VEGF*, *GLUT1*, *PDGF*) that support tumor growth and neovascularization. **(B)** When *VHL* is mutated and pVHL is unable to bind HIF- α , HIF- α stabilization leads to transcriptional upregulation of HIF target genes. (From Linehan WM, Srinivasan R, Schmidt LS. The genetic basis of kidney cancer: a metabolic disease. *Nat Rev Urol* 2010;7:277–285.)

Additional Genes for Clear Cell Kidney Cancer

Studies using next-generation sequencing approaches to identify the genetic basis of clear cell kidney cancer have revealed a considerable number of genetic alterations in chromatin remodeling genes important for the maintenance of chromatin states. Significantly mutated genes identified in sporadic clear cell kidney cancer in addition to *VHL* include *PBRM1*, a subunit of the PBAF SWI/SNF chromatin remodeling complex (41%),³³ histone methyl transferase *SETD2* (4%)³⁴ histone demethylases *JARID1C* (*KDM5C*; 3%)³⁵ and *UTX* (*KDM6A*; 3%),³⁵ and the novel tumor suppressor gene, *BAP1* (15%),³⁶ a histone deubiquitinase. *BAP1* is also mutated, albeit rarely, in the germ line of inherited clear cell kidney cancer families^{37,38} and is associated with poor survival outcome.³⁹

HEREDITARY PAPILLARY RENAL CARCINOMA TYPE 1

HPRC is an autosomal-dominant hereditary cancer syndrome in which affected individuals are at risk for the development of multifocal, bilateral papillary type 1 kidney cancer.⁴⁰ HPRC develops in the 5th and 6th decades, with age-dependent penetrance estimated at 67% by 60 years of age⁴¹; however, early-onset HPRC has been described.⁴² This rare disorder has been reported in less than 40 kindreds worldwide.⁴⁰

Genetics of Hereditary Papillary Renal Carcinoma: *MET* Proto-oncogene

In 1995, Zbar et al.⁴³ described 10 families in which multifocal, bilateral papillary renal tumors were inherited in an autosomal-dominant fashion and suggested that these families might represent a hereditary counterpart to sporadic papillary tumors. Schmidt et al.⁶ localized the HPRC disease locus to chromosome 7q31.1-34 by genetic linkage analysis. Because the trisomy of chromosome 7 was described as a hallmark feature of papillary renal tumors,⁴⁴ a gain-of-function oncogene seemed a likely candidate disease gene; in fact, germ-line missense mutations were identified in the tyrosine-kinase domain of the *MET* protooncogene located at 7q31 in affected HPRC family members.⁶ Mutations of the *MET* gene have been detected in 13% of sporadic papillary renal tumors.^{6,45} Further studies to determine the role of *MET* and related genes in papillary type 1 kidney cancer are currently under way.

Hereditary Papillary Renal Carcinoma: Functional Consequences of *MET* Mutations

The *MET* protooncogene encodes the hepatocyte growth factor/scatter factor (HGF/SF) receptor tyrosine kinase. Binding of ligand HGF to *MET* triggers autophosphorylation of critical tyrosines in the intracellular tyrosine kinase domain, subsequent phosphorylation of tyrosines in the multifunctional docking site, and recruitment of a variety of transducers of downstream signaling cascades that regulate cellular programs leading to cell growth, branching morphogenesis, differentiation, and “invasive growth.”⁴⁶ Although *MET* overexpression has been demonstrated in a number of epithelial cancers,⁴⁷ HPRC was the first cancer syndrome for which germ-line *MET* mutations were identified. The missense *MET* mutations in HPRC are constitutively activating without ligand stimulation, display oncogenic potential in vitro,^{48,49} and are predicted by molecular modeling to stabilize active *MET* kinase.⁵⁰ Nonrandom duplication of the chromosome 7 bearing the mutant *MET* allele was demonstrated in papillary renal tumors from HPRC patients⁵¹ and may represent the second step in HPRC tumor pathogenesis. The presence of two copies of mutant *MET* may give kidney cells a proliferative growth advantage and lead to tumor progression.

XP11.2 TRANSLOCATION RENAL CELL CANCER

Xp11.2 translocation renal cell carcinomas, typically presenting with papillary architecture and clear or eosinophilic cytoplasm, are rare tumors in adults (1.6%), but are the cause of 20% to 45% of renal cancers in children and young adults. Translocations involving Xp11.2 and 1q21.2 associated with sporadic papillary renal carcinoma, and first described in a 2-year-old child,⁵² generate a fusion between a novel gene, *PRCC*, and the basic helix-loop-helix-leucine zipper transcription factor gene, *TFE3*, a member of the microphthalmia (MiT) family of transcription factors.⁵³ The encoded fusion protein, *PRCC-TFE3*, acts as a stronger transcriptional activator than native *TFE3*, and a loss of the majority of native *TFE3* transcripts is observed in these tumors. This deregulation of normal *TFE3* transcriptional control caused by the chromosomal translocation may be important to the development of sporadic papillary renal cell carcinoma.^{54,55} Xp11.2 translocation renal cell carcinomas involving at least five different *TFE3* gene fusions and resulting in deregulation of *TFE3* transcription activity have been described, including *NonO-TFE3*, *PSF-TFE3*, *CLTC-TFE3*, and *ASPL-TFE3*.⁵⁶ Tsuda et al.⁵⁷ have shown that these *TFE3* fusion proteins are strong transcriptional activators of the *MET* gene, resulting in inappropriate *MET*-directed cell proliferation and invasive growth. Given the physiologic consequences of *TFE3* fusion protein expression, therapeutic targeting of *MET* may be an effective treatment for Xp11.2 translocation renal tumors.

The fusion of another member of the MiT family, *TFEB*, with the *Alpha* gene has been described in renal tumors harboring t(6;11)(p21;q13) chromosomal translocation.⁵⁸ The first case of renal cancer involving a third MiT family member, *MITF*, was recently reported, in which an activating *MITF* mutation was identified in the germ-line of family members affected with renal tumors.⁵⁹

BIRT-HOGG-DUBÉ SYNDROME

BHD syndrome is a rare autosomal-dominant inherited cancer syndrome characterized by benign tumors of the hair follicle (fibrofolliculoma), pulmonary cysts and spontaneous pneumothorax, and a sevenfold increased risk for renal cancers.^{60–63} Fibrofolliculomas and lung cysts are the most common manifestations (>85%) of BHD patients.^{64–66} Renal tumors with variable histologies develop in about 30% of BHD-affected individuals (median age, 48 to 50 years), most frequently chromophobe renal carcinoma and hybrid oncocytic tumors.^{64,67} Metastases may develop from BHD renal tumors, but they are uncommon.

Genetics of Birt-Hogg-Dubé Syndrome: Folliculin Gene

A genetic linkage analysis performed in BHD kindreds led to the localization of the disease locus on the short arm of chromosome 17^{68,69} and the identification of the BHD gene, *FLCN*.⁸ Almost all BHD-associated *FLCN* mutations are predicted to truncate the BHD protein, folliculin, including insertion or deletion, nonsense, and splice-site mutations,^{8,64,65,70} but recently, several missense mutations located in conserved amino acid residues and partial gene deletions have been described.^{65,71–73} The mutation detection rate in several large BHD cohorts approached 90%, and germ-line mutations were distributed throughout the entire length of the *FLCN* gene with no clear genotype–phenotype correlations.^{64,65,74} Vocke et al.⁷⁵ identified second “hit” somatic mutations or LOH in 70% of renal tumors from BHD patients, supporting a role for *FLCN* as a tumor suppressor gene that predisposes individuals to renal tumors when both copies are inactivated. *FLCN* mutations have

Figure 62.2 The putative Birt-Hogg-Dubé gene (*FLCN*) pathway. **(A)** *FLCN* binds through FNIP1/2 to AMP-activated protein kinase (AMPK) and may become phosphorylated by AMPK or by a rapamycin-sensitive kinase (i.e., mTOR). **(B)** When *FLCN* is inactivated and, presumably, *FLCN* protein is absent, mTOR is dysregulated, potentially driving kidney tumor formation in BHD patients. (From Linehan WM, Srinivasan R, Schmidt LS. The genetic basis of kidney cancer: a metabolic disease. *Nat Rev Urol* 2010;7:277–285.)

been found infrequently in chromophobe renal cell carcinomas (11%),⁷⁶ and only rarely in other histologic variants of RCC.^{77–79}

Function of the Birt-Hogg-Dubé Protein: Folliculin

The *FLCN* gene encodes a novel protein, folliculin (FLCN), with no characteristic functional domains. Baba et al.⁸⁰ identified a novel FLCN-interacting protein, FNIP1, and showed that FNIP1 interacts with the γ subunit of 5' adenosine monophosphate (AMP)-activated protein kinase (AMPK), an energy sensor in cells that negatively regulates mammalian target of rapamycin (mTOR), the master switch for protein translation and cell proliferation, through TSC1/2.^{81,82} A second folliculin interacting protein, FNIP2, was subsequently identified that displayed similar biochemical properties to FNIP1.^{83,84} FLCN, through FNIP1/2, may play a role in the regulation of the AMPK-TSC1/2–mTOR signaling pathway (Fig. 62.2). Published data from *in vivo* models and BHD renal tumors, supporting mTOR activation^{85,86} as well as mTOR inhibition^{87–89} as a consequence of *FLCN* inactivation, has led to the hypothesis that the mechanism by which FLCN interacts with and modulates mTOR is context dependent.⁸⁹

Additional functional roles for FLCN in transforming growth factor β (TGF- β) signaling,^{90,91} modulation of HIF- α and its target genes,⁹² ciliogenesis,⁹⁵ peroxisome proliferator-activated receptor γ coactivator 1 α (PGC-1 α) regulation and mitochondrial biogenesis,^{94,95} cell–cell adhesion,^{96,97} exit from embryonic stem cell pluripotency,⁹⁸ and regulation of lysosome function through cytoplasmic sequestration of the transcription factors TFE3⁹⁹ and TFE3¹⁰⁰ have been reported. The resolution of C-terminal FLCN crystal structure has demonstrated structural homology to the

DENN domain, which has guanine exchange factor (GEF) activity toward RabGTPases.¹⁰¹ Two recent reports have shown FLCN/FNIP1/FNIP2 interaction with RagGTPases and proposed a role of this complex in amino acid sensing for mTOR activation.^{100,102} In addition to a role for FNIP1 in facilitating FLCN interaction with AMPK, *Fnip1* knockout mice displayed a defect in pro- to preB cell differentiation demonstrating a unique requirement for the FLCN-FNIP1 complex in B-cell development.¹⁰³

HEREDITARY LEIOMYOMATOSIS AND RENAL CELL CARCINOMA

HLRCC is an autosomal-dominant inherited disorder that predisposes individuals to the development of skin and uterine leiomyomas and an aggressive form of type 2 papillary renal carcinoma. Fewer than 150 HLRCC families have been reported worldwide.^{104,105} Renal tumors, which are often unilateral and solitary,^{104,106} may develop with early age of onset in 15% to 25% of affected individuals^{104,105} and can be aggressive, metastasize, and cause death within 5 years of diagnosis.

Genetics of Hereditary Leiomyomatosis and Renal Cell Carcinoma: Fumarate Hydratase Gene

A genetic linkage analysis localized the HLRCC disease locus to chromosome 1q42-43,¹⁰⁷ but an association with renal cancer was not appreciated until Launonen et al.¹⁰⁸ demonstrated a linkage to chromosome 1q in two Finnish multiple cutaneous and uterine leiomyomata (MCUL) kindreds with solitary, highly aggressive

papillary type 2 renal tumors. The disorder was renamed *hereditary leiomyomatosis and renal cell carcinoma* and the locus was subsequently mapped to a 1.6-Mb region of 1q42. Germ-line mutations were identified in the fumarate hydratase (FH) gene, a Krebs cycle enzyme that converts fumarate to malate in HLRCC-affected family members.⁷ FH mutations in HLRCC include missense, frameshift, nonsense, and splice-site mutations, as well as partial and complete gene deletions.^{104,106,109,110} Missense mutations are the most common (57%) and occur mainly at evolutionarily conserved residues.^{106,109,110} Mutations are found throughout the entire length of the FH gene excluding exon 1, which encodes a mitochondrial signal peptide, and no clear genotype–phenotype associations have been reported.¹⁰⁴ FH acts as a classic tumor suppressor gene with a loss or somatic mutation of the wild-type FH allele at high frequency in renal tumors and skin and uterine leiomyomata.⁷ FH mutations are rarely detected in sporadic uterine and skin leiomyomata or sporadic RCCs.¹¹¹

Functional Consequences of Fumarate Hydratase Mutations

FH mutations reduce FH activity by 20% to 80%^{7,109,112} in lymphoblastoid cell lines from HLRCC patients. HLRCC-associated

missense mutations significantly lowered FH activity compared to truncating mutations,¹⁰⁹ suggesting that mutant FH monomers might act in a dominant negative manner to alter proper conformation of FH tetramers. Loss of FH activity in HLRCC leads to accumulation of fumarate and, to a lesser extent, succinate, due to a block in the Krebs cycle.^{113,114} Pollard et al.¹¹³ have confirmed that the accumulation of fumarate and succinate resulted in the elevation of HIF-1 α and HIF-target genes (*VEGF*, *BNIP*), and increased microvessel density¹¹⁵ in HLRCC-associated uterine fibroids. Isaacs et al.¹¹⁴ showed that stabilization of HIF-1 α resulted from the competitive inhibition of the HIF PHD co-substrate, α -ketoglutarate, by fumarate accumulation, leading to the abrogation of PHD function and release of HIF-1 α from proteasomal degradation. This pseudohypoxic drive, resulting from loss of FH activity, HIF-1 α stabilization, and upregulation of HIF-inducible genes, contributes to the aggressive nature of HLRCC-associated renal tumors (Fig. 62.3). Xiao et al.¹¹⁶ have demonstrated that accumulated fumarate and succinate can act as competitive inhibitors of multiple α -ketoglutarate-dependent dioxygenases, including histone demethylases and the ten-eleven translocation (TET) family of 5-methylcytosine hydroxylases leading to more global alterations in histone and DNA methylation. Additionally, Sudarshan et al.¹¹⁷ showed that FH mutations in an HLRCC-derived cell line led to glucose-mediated generation of

Figure 62.3 Fumarate hydratase (FH)–deficient kidney cancer, an aggressive form of type 2 papillary kidney cancer, is found in patients affected with the hereditary cancer syndrome, HLRCC. FH-deficient kidney cancer is characterized by a metabolic shift to aerobic glycolysis. Mitochondrial function is impaired by a decrease in FH function, and the cell depends on aerobic glycolysis for adenosine triphosphate (ATP) production needed for rapid growth. The increased ATP leads to decreased activation of AMPK, which results in increased mTOR/phosphoS6 activity and increased Acetyl CoA carboxylase (ACC)/fatty acid production. Increased fumarate, a result of decreased fumarate hydratase activity, inhibits HIF PHD, resulting in increased HIF1 α levels. The increased fumarate also inhibits KEAP1 activity, resulting in increased Nrf2 transcriptional activity that is critical for the survival of these cells, which are characterized by high oxidative stress. (From Linehan WM, Rouault TA. Molecular pathways: fumarate hydratase-deficient kidney cancer: targeting the Warburg effect in cancer. *Clin Cancer Res* 2013;19:3345–3352.)

reactive oxygen species (ROS) and ROS-dependent HIF-1 α stabilization, supporting an alternate mechanism by which pseudohypoxic drive could support renal tumorigenesis in HLRCC. Further, Sullivan et al.¹¹⁸ determined that the increase in ROS was due to the succination of antioxidant glutathione by accumulated fumarate (see the following) to produce the oncometabolite succinated glutathione, an alternate substrate to glutathione reductase, resulting in a decrease in NADPH levels, enhanced ROS and HIF1- α activation.

Recent *in vivo* and *in vitro* evidence supports a role for fumarate accumulation in activation of the nuclear factor (erythroid-derived 2)-like 2 (Nrf2)-mediated antioxidant signaling pathway.¹¹⁹ Kelch-like erythroid-derived Cap-n-Collar homology (ECH)-associated protein 1 (KEAP1), an electrophile sensor and substrate recognition site for cullin-3 (CUL3)-based E3 ubiquitin ligase, binds to Nrf transcription factors under low electrophile conditions facilitating interactions with CUL3 for ubiquitin-mediated degradation. However, intracellular accumulated fumarate in FH-deficient kidney cancer (HLRCC) reacts with exposed cysteines on the KEAP1 protein (*succination*), resulting in a conformational change that inhibits KEAP1-Nrf2 binding (see Fig. 62.3). Consequently Nrf2 becomes available for transcriptional activation of its target genes that are regulated through antioxidant response elements (ARE) in their promoters.^{120,121} In support of this model, somatic inactivating mutations in *KEAP1* and *CUL3*, and activating mutations in *NRF2*, have been identified in sporadic papillary RCC type 2.¹²² Inhibiting upregulated Nrf2-target genes (i.e., heme oxygenase 1 [HMOX1], which is important for heme oxygenation)¹²³ that promote cancer cell survival may provide a novel therapeutic approach to HLRCC and sporadic PRCC2 treatment.

Finally, cells normally generate energy through the Krebs cycle coupled to oxidative phosphorylation, but FH-deficient kidney cancer cells lack the enzyme to convert fumarate to malate, resulting in a block in the Krebs cycle. Mullen et al.¹²⁴ showed that FH-deficient kidney cancer cells that lack a fully functional electron transport chain use glutamine-dependent reductive carboxylation via isocitrate dehydrogenases 1 and 2 to produce acetyl coenzyme A (CoA) for lipid synthesis and Krebs cycle intermediates. Metabolic reprogramming of FH-deficient kidney cancer cells enables the elevated production of ribose from glucose via increased flux through the pentose phosphate pathway to meet the high demand for nucleotides.¹²⁵

FAMILIAL RENAL CANCER: SUCCINATE DEHYDROGENASE GENE

Bilateral multifocal renal tumors with early onset (<40 years of age) have been reported in the setting of hereditary head and neck paragangliomas (HPGL) and adrenal or extra-adrenal pheochromocytomas.⁹ Most frequently, a unique form of oncocytic RCC develops; however, clear cell RCC, chromophobe RCC, papillary type 2 RCC, and renal oncocytoma have been described.^{126–128}

Genetics of Familial Renal Cancer: Succinate Dehydrogenase Subunit B and D Mutations

Germ-line mutations in the gene encoding succinate dehydrogenase subunit D (SDHD) were initially associated with HPGL

and later with familial and sporadic pheochromocytomas.^{129,130} Subsequently, inactivating mutations in *SDHB* were found in kindreds with familial pheochromocytoma only and with HPGL, and in one case of sporadic pheochromocytoma.¹³¹ Later, early onset clear cell RCC was diagnosed in two individuals with HPGL and germ-line *SDHB* mutations.⁹ Renal carcinomas with various histologies have been reported in patients with germ-line missense, frameshift, and nonsense mutations in *SDHB*, *C*, and *D*.^{10,11,126–128,132}

Functional Consequences of Succinate Dehydrogenase Subunit B and D Mutations

Mutational inactivation of the *SDH* gene results in reduced SDH enzyme activity and the accumulation of succinate in renal tumors. In a mechanism similar to *FH* mutations in HLRCC (see Fig. 62.3), the accumulation of succinate serves to competitively inhibit α -ketoglutarate and block PHD activity.^{113,114} In the absence of PHD, HIF- α accumulates and drives transcriptional activation of HIF- α target genes that support tumor neovascularization, growth, and invasion.

TUBEROUS SCLEROSIS COMPLEX

The tuberous sclerosis complex (TSC) is a multisystem, autosomal-dominant disorder affecting both children and adults and is characterized by facial angiofibromas, renal angiomyolipomas, lymphangiomyomatosis of the lung, and disabling neurologic manifestations. The disease is phenotypically heterogeneous, and many patients have only minimal symptoms of disease.¹³³

The predominant renal manifestations in TSC are bilateral multifocal angiomyolipomas (AML), benign tumors composed of abnormal vessels, immature smooth muscle cells, and fat cells. The lifetime risk of renal cancer in TSC patients is 2% to 3%, which is similar to the general population.¹³³ The most common histologic type of renal tumor is clear cell; however, there are rare reports of papillary RCCs, chromophobe RCCs, and oncocytoma in TSC patients.¹³³ TSC is caused by mutations in one of two genes—*TSC1* that encodes hamartin¹³⁴ or *TSC2* that encodes tuberin¹³⁵—leading to a loss of TSC1/2-negative regulation of mTOR signaling.^{81,82,136} Drug therapy targeting the mTOR pathway may be most effective for treating TSC-associated AMLs and renal tumors.¹³⁷

CONCLUSION

Twelve renal cancer predisposing genes—*VHL*, *MET*, *FLCN*, *TFE3*, *TFEB*, *MITE*, *TSC1*, *TSC2*, *PTEN*, *FH*, *SDHB*, and *SDHD*—have been identified mainly through studies of inherited renal cancer syndromes, including VHL, HPRC, BHD, HLRCC, SDH-related familial renal cancer, and TSC (Fig. 62.4). These studies have provided valuable insight into the genetic events that lead to the development of renal tumors and the biochemical mechanisms that contribute to their progression and, ultimately, in some cases, to metastasis. These findings have enabled the development of diagnostic genetic testing and provided the foundation for the development of targeted therapeutic agents for patients with the common form of sporadic kidney cancer.

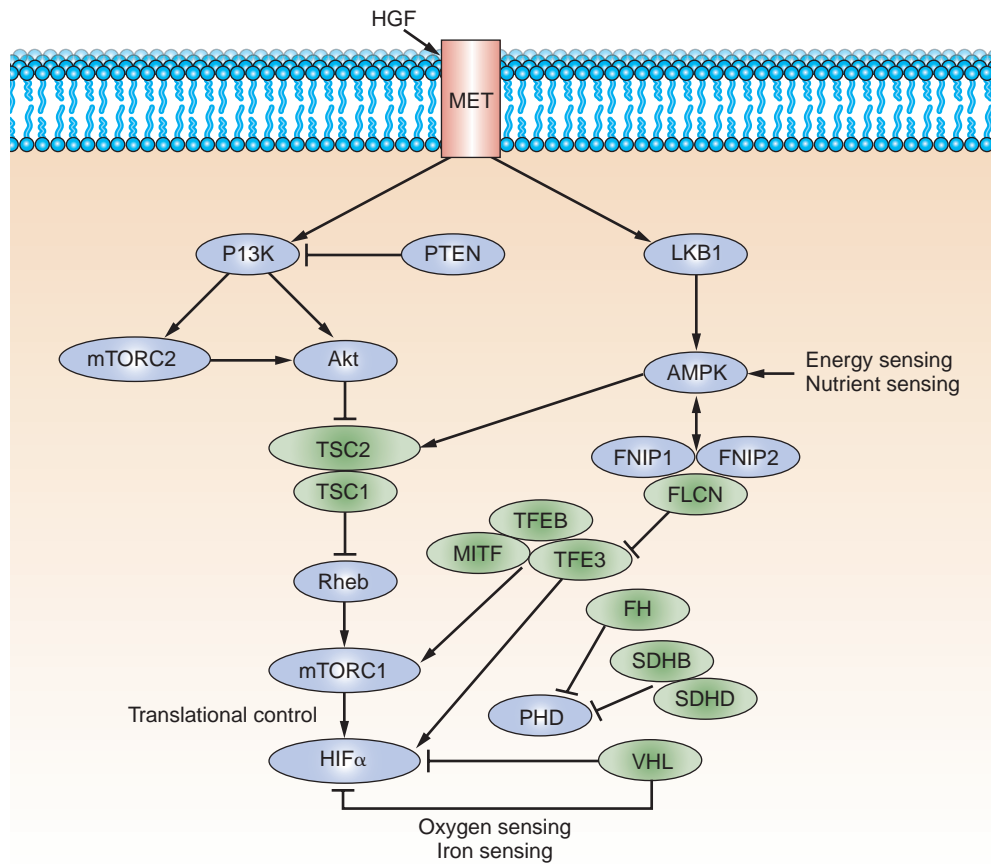

Figure 62.4 The genetic basis of kidney cancer. Twelve renal cancer predisposing genes—*VHL*, *MET*, *FLCN*, *TFE3*, *TFEB*, *MITF*, *TSC1*, *TSC2*, *PTEN*, *FH*, *SDHB*, and *SDHD*—have been identified mainly through studies of inherited kidney cancer syndromes. These genes interact through common oxygen, iron, nutrient, and energy sensing pathways and demonstrate that kidney cancer is fundamentally a metabolic disease. Our understanding of the molecular mechanisms by which these genes interact in these pathways has enabled the development of targeted therapeutic agents to benefit kidney cancer patients. (From Linehan WM, Ricketts CJ. The metabolic basis of kidney cancer. *Semin Cancer Biol* 2013;23:46–55.)

63 Cancer of the Kidney

Brian R. Lane, Daniel J. Canter, Brian I. Rini, and Robert G. Uzzo

INTRODUCTION

Cancer of the kidney is neither common enough to cause a large percentage of cancer-related deaths nor uncommon enough to be considered an “orphan” malignancy. In that context, the progress made in uncovering the genetic basis of renal cell carcinoma (RCC), its molecular pathways, and the approval of novel therapies to perturb those pathways over the last decade is indeed remarkable. Over a relatively short time, the management options for localized kidney cancer have evolved from near universal acceptance of open radical nephrectomy (RN) to the routine use of minimally invasive partial nephrectomy (PN), thermal ablation (TA), and active surveillance (AS). Concurrently, metastatic RCC has progressed from marginally treatable, with a low incidence of spontaneous and/or immune-induced durable regression, to overall response rates (complete response + partial response + stable disease) of >50% and a near doubling of cancer-specific survival. Looking forward, it is anticipated that kidney cancer will soon become a chronic disorder as we better understand the biologic heterogeneity and systemic therapies for RCC. Herein, we review the current and rapid evolution in our understanding and management of cancer of the kidney.

EPIDEMIOLOGY, DEMOGRAPHICS, AND RISK FACTORS

Kidney cancer accounts for approximately 2% of malignancies worldwide with about 300,000 cases diagnosed per year and 100,000 deaths.¹ Data suggest the incidence of RCC is more common in industrialized countries, which may be related to increased incidental detection. In the United States, tumors of the kidney account for 3% to 4% of all cancer diagnoses with an estimated 65,000 cases and 14,000 deaths.² There is a male-to-female predominance with the lifetime risk of a RCC diagnosis of 1:69 in men and 1:116 in women.³ While kidney cancer remains predominantly a tumor of the elderly (median age at diagnosis of 65 years), the number of new kidney cancer cases appears to be rising in younger individuals.² This may be explained by either the increasing use of noninvasive imaging in younger patients⁴⁻⁶ or perhaps true biologic differences in the disease.⁷ Similarly, racial differences have also been described with increased rates and decreased survival noted in African Americans and improved survival in Asian populations.⁸ Whether this represents differences in health-care access or disease biology is unclear.

The most commonly cited risk factors for the development of RCC include smoking, obesity, and hypertension.⁹ The data regarding smoking as a risk factor for RCC appear strong. In a meta-analysis evaluating 19 case control studies and 5 cohort studies, Hunt et al.¹⁰ found a 38% increased risk in current and former smokers, noting not only a dose-risk relationship, but also an abatement of risk with smoking cessation >10 years. The relationship between obesity and RCC is less well studied, although the epidemiology seems to point to a causal association. In a quantitative review of the literature between 1966 and 1998, Renehan et al.¹¹

calculated a relative risk of 1.07 per increase in unit body mass index and concluded that nearly a third of RCC cases may be attributable to obesity. Data suggesting a stronger association of obesity and RCC in women lead to hypotheses that the relationship may be due to dysregulation of sex hormones, insulin metabolism, or the immune system.³ The relationship between hypertension and RCC is based largely upon retrospective and/or population-based epidemiologic data. In an analysis of 13 case controlled studies, Grossman et al.¹² noted hypertensive patients exhibited a pooled odds ratio of 1.75 of having RCC. While there may be a relationship between severity and duration of hypertension, given the limits of the data, if such an association exists it is difficult to ascertain.³ Finally, exposure to chronic diuretics,¹³ nonsteroidal analgesics,¹⁴ and trichlorethylene, a cleaning agent, have all been associated with an increased risk of RCC.³

While screening for kidney and other potentially lethal diseases is enticing, a risk benefit analysis argues against it given the low overall prevalence of RCC in the general population. One large study, in which over 200,000 adults were screened for abdominal malignancy with ultrasound, found only 192 cases of RCC (0.09%).¹⁵ Screening has, therefore, been proposed in target populations, including individuals with familial RCC syndromes such as von Hippel-Lindau disease (VHL) and those on hemodialysis, who are known to be more likely to be diagnosed with RCC. In patients on dialysis, while there appears to be an increased incidence of RCC in the native kidneys or even in a transplanted allograft, this may be due to their medical follow-up. Indeed, most patients with end-stage renal disease will have been “screened” during the evaluation and management of their renal failure/allograft, making the reasons for this association difficult to dissect. This is distinctively different than an emerging population of patients with increased genetic risk for cancer, but whose kidneys have not yet been imaged. In families who carry known mutations in the genes responsible for VHL, hereditary papillary RCC, hereditary leiomyoma RCC, Birt-Hogg-Dubé syndrome (BHD), potentially tuberous sclerosis, and/or autosomal dominant polycystic kidney disease, a renal ultrasound may be an inexpensive, low-risk, and judicious means of targeted screening. The initial timing, frequency, and effectiveness of screening in these at-risk populations are not yet established.

PATHOLOGY OF RENAL CELL CARCINOMA

Pathologic classifications assist in diagnosis and prognosis, and inform therapy. Most pathologic classifications emphasize a tumor’s morphology and histology—although, increasingly they are incorporating genetic characteristics.¹⁶ There are 10 tumor subtypes in the current World Health Organization classification system for RCC (Table 63.1). The major histologic variants include clear cell, papillary, chromophobe, and collecting duct tumors, which account for 90% to 95% of renal carcinomas,¹⁷ although less common subtypes and an “unclassified” category also exist. Uncommon subtypes of RCC, not included in the World Health Organization classification, include tubulocystic carcinoma, clear

TABLE 63.1

2004 World Health Organization Classification of Sporadic Renal Cell Carcinoma with Genetic and Clinical Correlates

Type	Genetics	Clinical
ccRCC (70% to 80%)	Deletion, mutation or methylation of 3p25-26 (<i>VHL</i>)	Most common variant Prognosis predicted by stage and grade
Multilocular cystic ccRCC (uncommon)	Deletion, mutation, or methylation of 3p25-26 (<i>VHL</i>)	Variant of ccRCC Distant metastases uncommon
Papillary RCC (10% to 15%)	Gain of 7 or 17 (trisomy or tetrasomy), loss of Y, deletion of 9p. Mutations of 7q31 when associated with hereditary papillary RCC	10% to 15% of RCC 95%+ 5-year cancer-specific survival in type I papillary RCC Response to tyrosine-kinase inhibitors less robust
Chromophobe RCC (3% to 5%)	Extensive chromosomal loss of Y, 1, 2, 6, 10, 13, 17, 21 Mutations of 17p11.2 when associated with BHD	5% of RCC Affects men and women equally with overall excellent prognosis
Collecting duct carcinoma (Bellini tumor) (<1%)	Highly variable Losses of 1q, 6p, 8p, 9p, 13q, 19q, 21q	Male preponderance (2:1) Mean age 55 Microscopically high grade, may resemble urothelial spectrum of cancers, Overall poor prognosis
Renal medullary carcinoma (rare)	Not defined	Associated with sickle cell trait Aggressive and lethal within 12 mo Mean age 19 y Male>female
Xp11 translocation carcinoma (rare)	Translocation of TFE3 gene on XP11.2	Children and young adults May present at advanced state and act more aggressively in adults
Renal carcinoma associated with neuroblastoma (rare)	Not defined	Morphologically and microscopically similar to ccRCC
Mucinous tubular and spindle cell carcinoma (rare)	Not defined	Female preponderance (4:1) Rarely metastasize
Unclassified RCC (1% to 3%)	Varied	Generally poor prognosis

ccRCC, clear cell renal cell carcinoma; RCC, renal cell carcinoma.

cell tubulopapillary RCC, thyroid-like follicular carcinoma, and acquired cystic disease–associated RCC. The relatively rapid movement in RCC toward molecular classification follows advances in our molecular understanding of these variants and may soon supplant simple morphologic classification.

Other pathologically relevant variables in RCC include nuclear grade, sarcomatoid and rhabdoid differentiation, tumor necrosis, and vascular invasion. Nuclear grade usually follows the Fuhrman grading system¹⁸ and is most often and best used for clear cell RCC (ccRCC) as the prognostic value in non-ccRCC remains largely unproven. Sarcomatoid differentiation exists in 5% of RCC and can be seen in any subtype. As such it is not considered a distinct entity, but rather a high-grade or poorly differentiated component. The presence and extent of micro- or macronecrosis has been correlated with prognosis in ccRCC.¹⁹ Micro- or macrovascular invasion is thought to be a requisite step toward systemic disease; however, correlation between the extent of invasion and prognosis remains imprecise.

DIFFERENTIAL DIAGNOSIS AND STAGING

Most patients with RCC present with an incidental, radiographically detected renal mass (Fig. 63.1). While symptoms including microscopic or gross hematuria, flank pain, gastrointestinal disturbances and/or pain, bleeding or systemic disturbances related to metastases may lead to the diagnosis, the use of routine cross-sectional imaging has led to the more common scenario of

an incidentally detected renal mass. While the suspicion for RCC may be high in cases such as these, RCC is a pathologic/tissue diagnosis, not a clinical one (Fig. 63.2). Proper radiographic evaluation of a renal mass requires a pre- and postcontrast computed tomography or magnetic resonance imaging (MRI) to assess enhancement.²⁰ Duplex ultrasound, renal mass biopsy, and non-contrast diffusion-weighted MRI with antibody drug conjugates mapping may be useful adjunctive tests in various clinical settings. deoxy-2[¹⁸F]fluoro-d-glucose positron emission tomography exhibits a low sensitivity for the diagnosis of RCC and is therefore not recommended for the evaluation of RCC. ImmunoPET with G-250 using an iodine-labeled antibody against carbonic anhydrase IX (CA-IX), which is known to be overexpressed in ccRCC, exhibits near 90% sensitivity and specificity for this RCC subtype.²¹

The differential diagnosis of the renal mass is broad and includes a long list of benign, malignant, and inflammatory conditions. Clinical and radiographic features can assist the astute clinician in narrowing down the diagnosis of the renal mass, particularly for benign and inflammatory lesions. Cystic lesions, for example, are frequently benign,²² and fat-containing solid lesions are most commonly found to be angiomyolipomas (also benign). About 20% of enhancing renal masses and 15% of surgically removed masses are nonmalignant, with the most common diagnoses being oncocytoma and fat-poor angiomyolipoma.^{23–25} Young to middle-aged women, in particular, are more likely to have benign pathology, as high as 40% in some series, while the likelihood of malignancy gradually decreases with age in men.^{24,26} Tumor size is the most

Figure 63.1 Cross-sectional imaging of kidney cancer using computed tomography and magnetic resonance imaging. **(A)** Contrast-enhanced computed tomography imaging (parenchymal phase) reveals a left renal mass with tumor thrombus within the left renal vein. **(B)** Magnetic resonance imaging in the same patient shows that the renal vein thrombus extends within the renal vein, but not to the confluence with the inferior vena cava (level 0 thrombus). m, mass; v, vein.

important determinant of pathology and biologic aggressiveness with larger tumors more likely to be high grade, locally invasive, and/or of adverse histologic subtype.^{23,24,27} Incorporation of readily available features can allow the physician to provide an individualized risk of cancer (ranging between ~50% and ~99%), but a certain diagnosis requires pathologic confirmation.^{24,28} The most accurate nomogram currently available gives estimates of preoperative prediction of tumor histology with an area under the curve of 0.76 and high-grade malignancy with an area under the curve of 0.73.²⁸

Percutaneous renal mass sampling is now being performed with increased regularity at many centers.²⁹ There is a strong rationale for biopsy when the findings will change management, such as when there is reason to suspect lymphoma/leukemia or abscess or to guide systemic therapy for metastatic disease. Even for clinically localized renal tumors, conventional renal mass biopsy can provide a definitive diagnosis in 80% to 90% of cases, and the ability to subtype and grade RCC can increase with the use of immunohistochemical and other molecular analyses.^{30,31} Therefore, renal mass sampling should be considered in patients with enhancing renal masses who are candidates for a wide range of management strategies.^{30–34} However, younger, healthier patients who are unwilling to accept the uncertainty associated with renal mass biopsy as well as elderly, frail patients who will be managed conservatively (independent of biopsy results) should still be managed without a biopsy.

Clinical and pathologic staging systems provide a basis of standardized communication, comparison, and prognostication. They

are used to communicate risk for treatment decision making and clinical trials planning. There have been several staging systems for RCC proposed. The most widely used is version 7 of the TNM (tumor, node, metastasis) staging system of the American Joint Committee on Cancer and the Union for International Cancer Control, updated in 2010 (Table 63.2). It distinguishes T1a from T1b and T2a from T2b based on tumor size.³⁵ Additionally, adrenal involvement was changed from pathologic stage T3a to T4 and venous invasion was separated into renal vein/segmental branches (T3a) and inferior vena cava (IVC) below (T3b) or above the diaphragm (T3c). Nodal and metastatic disease are only classified as negative (N0/M0) or positive (N1/M1). Other potential prognostic features of the primary tumor not included in the TNM classification include necrosis, urothelial involvement, microvascular invasion and molecular features. Review of these and other prognostic features of RCC are available.³⁶

HEREDITARY KIDNEY CANCER SYNDROMES, GENETICS, AND MOLECULAR BIOLOGY

While most renal cancers are believed to occur sporadically, familial clusters have led to the discovery of at least seven RCC susceptible syndromes (Table 63.3). It is estimated that approximately 4% of RCC have a hereditary basis.³⁷ In these cases, in addition to a provocative family history, tumors tend to be bilateral,

Histological type:	Clear cell	Papillary type 1	Papillary type 2	Chromophobe	Oncocytoma	Angiomyolipoma	TFE3	Oncocytic	Clear/chromophobe
Hereditary gene:	VHL	Met	FH	FLCN		TSC1, TSC2	MITF	SDHB, SDHD	PTEN
Sporadic gene:	VHL (89%)	Met (89%)	TBD*	TBD*		TSC1, TSC2	TFE3, TFEB	TBD*	TBD*

Figure 63.2 Human renal epithelial neoplasms. Renal cortical tumors do not conform to a single pathology. There are a number of different tumor subtypes that display the full range of oncologic activity, ranging from benign to indolent to aggressive. Each histologic type is characterized by distinct gross and microscopic appearance, gene associated with their familial forms, and genetic changes commonly detected in sporadic cases. TABLE 63.2

International Tumor, Node, Metastasis Staging System for Renal Cell Carcinoma and Survival Rates

T: Primary Tumor		Five-Year Survival (%)	
TX	Primary tumor cannot be assessed		
T0	No evidence of primary tumor		
T1a	Tumor ≤4 cm and confined to the kidney	90–100	
T1b	Tumor >4 cm and ≤7 cm and confined to the kidney	80–90	
T2a	Tumor >7 cm and ≤10 cm and confined to the kidney	65–80	
T2b	Tumor >10 cm and confined to the kidney	50–70	
T3a	Tumor grossly extends into the renal vein or its segmental (muscle containing) branches, or tumor invades perirenal and/or renal sinus fat but not beyond Gerota fascia	40–65	
T3b	Tumor grossly extends into the vena cava below the diaphragm	30–50	
T3c	Tumor grossly extends into the vena cava above the diaphragm or invades the wall of the vena cava	20–40	
T4	Tumor invades beyond Gerota fascia (including contiguous extension into the ipsilateral adrenal gland)	0–20	
N: Regional Lymph Nodes			
NX	Regional lymph nodes cannot be assessed		
N0	No regional lymph nodes metastasis		
N1	Metastasis in regional lymph node(s)	0–20	
M: Distant Metastases			
MX	Distant metastasis cannot be assessed		
M0	No distant metastasis		
M1	Distant metastasis present	0–10	
Stage Grouping			
Stage I	T1	N0	M0
Stage II	T2	N0	M0
Stage III	T3	Any N	M0
	T1 or T2	N1	M0
Stage IV	T4	Any N	M0
	Any T	Any N	M1

multifocal, and arise at an early age of onset. Importantly, the study of hereditary kidney cancer has dramatically changed our understanding of the genetic and molecular basis of RCC and has led to the development of effective, approved therapeutic agents as similar cytogenetic and molecular alterations appear to be shared between sporadic and hereditary RCC (see Fig. 63.2).³⁸

The molecular alterations in RCC appear to converge on similar pathways involved in dysregulated oxygen sensing/angiogenesis, iron metabolism, and energy/nutrient sensing.^{39,40} The predominant genetic and molecular defects in RCC known to date include VHL loss of function (ccRCC), neurofibromatosis type 2 loss of function (ccRCC), MET gain of function (papillary type I RCC), NRF2 gain of function and alterations in fumarate hydratase (papillary type II RCC), CCND1 gain of function and folliculin loss of function (oncocyoma/chromophobe RCC), and MiTF-TFE3 gain of function (translocation RCC). Additionally, inactivation of chromatin modifying proteins including *PBRM1*, *BAP1*, and histone methylases/demethylases, as well as inactivation of electron transporters, may represent early or common events in multiple subtypes.⁴¹ While important, the associations of these aberrant pathways with various subtypes of RCC likely represent an overly simplified model of renal tumor development.⁴² A variety of small nucleotide mutations, structural mutations, and large chromosomal abnormalities characterizes RCC, with as many as 5 to 70 small somatic mutations found in individual renal tumor cells.⁴² Moreover, variable gene expressions may reflect differences in cell types from which RCC originates, suggesting that genetic aberrations require a specific cellular context for dysregulated growth. The development of rapid sequencers continues to redefine the molecular characterization of RCC from which a genetic profile/classification is emerging with important implications for the development of the next generation of targeted therapeutic molecules.^{43,44}

Von Hippel-Lindau Disease

VHL is a syndrome characterized by the development of highly vascular tumors of the retina, central nervous system, pancreas, adrenal, and kidney (ccRCC). It is inherited in an autosomal dominant fashion with an incidence of 1:35,000.³⁹ Loss of VHL function (3p25.1) by genetic or epigenetic means in a classic tumor suppressor fashion is the known cause. In an established genotype-phenotype relationship, type I VHL (absence of pheochromocytoma) is due to germline deletions, insertions, and nonsense mutations, whereas type II VHL (with pheochromocytoma) is associated with missense mutations.⁴⁵ Between 25% to 60% of patients with VHL develop bilateral multifocal cystic and solid RCC, which represents a common cause of death (Fig. 63.3). Management of renal tumors in patients with VHL now includes surveillance of smaller tumors (<3 cm) and resection of larger ones (>3 cm) by PN with the goal of preventing metastases and optimizing renal function by “resetting the biologic clock” through appropriately timed surgeries.⁴⁶ The goal of complete tumor removal with wide negative surgical margins is less appropriate for these patients where management of localized lesions supplants cure.^{39,46} Patients should be evaluated and followed by a team of clinicians familiar with the complexities of multisystem genetic disorders.

Hereditary Papillary Renal Cell Carcinoma

Hereditary papillary RCC is perhaps the least common familial RCC syndrome, with manifestations that appear to only affect the kidney. Affected individuals develop bilateral multifocal type I papillary RCC due to mutations in the *MET* gene located at 7q31. *MET* is a tyrosine kinase receptor with hepatocyte growth factor as its ligand.⁴⁷ The syndrome is transmitted in an autosomal dominant fashion and tumors usually appear after the age of 30.³⁹ As with VHL, management of renal tumors recognizes the need to remove larger lesions and observe smaller ones. While no size cutoff for intervention has been established, the biology of type I papillary RCC appears to be more indolent than ccRCC,

TABLE 63.3

Familial Renal Cell Carcinoma Syndromes

Syndrome	Gene (Chromosome)	Major Clinical Manifestations
von Hippel-Lindau	VHL gene (3p25-26)	Clear cell RCC Retinal angiomas Central nervous system hemangioblastomas Pheochromocytoma Other tumors
Hereditary papillary RCC	<i>c-met</i> proto-oncogene (7q31)	Multiple, bilateral type 1 papillary RCCs
Familial leiomyomatosis and RCC	<i>Fumarate hydratase</i> (1q42-43)	Type 2 papillary RCC Collecting duct RCC Leiomyomas of skin or uterus Uterine leiomyosarcomas
Birt-Hogg-Dubé	<i>Folliculin</i> (17p11)	Multiple chromophobe RCC, hybrid oncocyctic tumor, oncocytomas Occasional clear cell (occasionally) Papillary RCC (occasionally) Facial fibrofolliculomas Lung cysts Spontaneous pneumothorax
Succinate dehydrogenase RCC	Succinate dehydrogenase complex subunits: <i>SDHB</i> (1p36.1-35) or <i>SDHD</i> (11q23)	Chromophobe, clear cell, type 2 papillary RCC, oncocytoma Paragangliomas (benign and malignant) Papillary thyroid carcinoma
Tuberous sclerosis	<i>TSC1</i> (9q34) or <i>TSC2</i> (16p13)	Multiple renal angiomyolipomas Clear cell RCC (occasionally) Renal cysts/polycystic kidney disease Cutaneous angiofibromas Pulmonary lymphangiomyomatosis
PTEN hamartoma tumor syndrome (Cowden syndrome)	<i>PTEN</i> (10q23)	Breast tumors (malignant and benign) Epithelial thyroid carcinoma Papillary RCC or other histology

PTEN, phosphatase and tensin homolog; RCC, renal cell carcinoma.

Adapted from Linehan WM, Walther MM, Zbar B. The genetic basis of cancer of the kidney. *J Urol* 2003; 170(6 Pt 1):2163-2172. and Linehan WM, Ricketts CJ. The metabolic basis of kidney cancer. *Semin Cancer Biol* 2013;23:46-55.

suggesting the risk of death from kidney cancer in these patients is low. Again, PN with renal preservation is emphasized despite the diffuse micro- and macromultifocality of these lesions.

Birt-Hogg-Dubé Syndrome

BHD is characterized by cutaneous fibrofolliculomas, a 50-fold increased risk of pneumothorax, and bilateral multifocal solid renal tumors. It is an autosomal dominant disorder with an incidence of around 1:200,000. Linkage analysis has mapped the gene for BHD (*folliculin*), a tumor suppressor, to 17p11.2. Folliculin is thought to be a downstream effector of activated protein kinase and mammalian target of rapamycin (mTOR).³⁹ Renal tumors associated with BHD are more indolent in nature, occurring in approximately 20% of individuals, with <5% developing metastases. While the histology of renal tumors associated with BHD is most often chromophobe RCC, oncocytoma, or hybrids of both, clear cell or papillary tumors may rarely occur as well.

Hereditary Leiomyomatosis Renal Cell Carcinoma

Hereditary leiomyomatosis RCC is also characterized by dermatologic manifestations. Patients with HLRCC exhibit cutaneous leiomyomas, early onset of uterine fibroids, macronodular adrenal hyperplasia, and kidney cancer. Linkage analysis has localized the HLRCC gene (*fumarate hydratase*), a key Krebs cycle enzyme, to 1p42.3 (FN).⁴⁸

Renal tumors in HLRCC tend to be aggressive and lethal. The most common histology observed is type II (eosinophilic) papillary RCC.³⁹ Unlike other hereditary forms of RCC, given the aggressive nature of these tumors, AS with delayed intervention is not recommended.

TREATMENT OF LOCALIZED RENAL CELL CARCINOMA

Greater use of cross-sectional imaging has contributed to earlier detection of RCC in many cases.^{2,49,50} Between 50% to 70% of RCC are detected incidentally,⁵¹ and the majority are “small renal masses (SRM),” or clinically localized renal cortical tumors up to 4 cm in size. Our perspectives about treatment of clinical T1 renal masses have changed substantially in the past 20 years. While all had been presumed to be malignant and managed aggressively, we now recognize the tremendous biologic heterogeneity of these lesions, and multiple management strategies are now available, including RN, PN, TA, and AS.⁵²⁻⁵⁷ Once controversial, elective PN is now accepted as a standard of care, based in part on the appreciation of the deleterious renal functional consequences of RN (Fig. 63.4).^{53,55,58} Ongoing analysis of the relative merits of PN, RN, and other management strategies has produced vibrant literature over the past few years.^{46,59-62} Both the American Urologic Association (AUA) and the European Association of Urology have released guidelines for the management of localized renal masses in recent years providing a robust analysis of the available studies.^{9,63-67} Each approach has associated risks and benefits, and no one approach is best in all circumstances

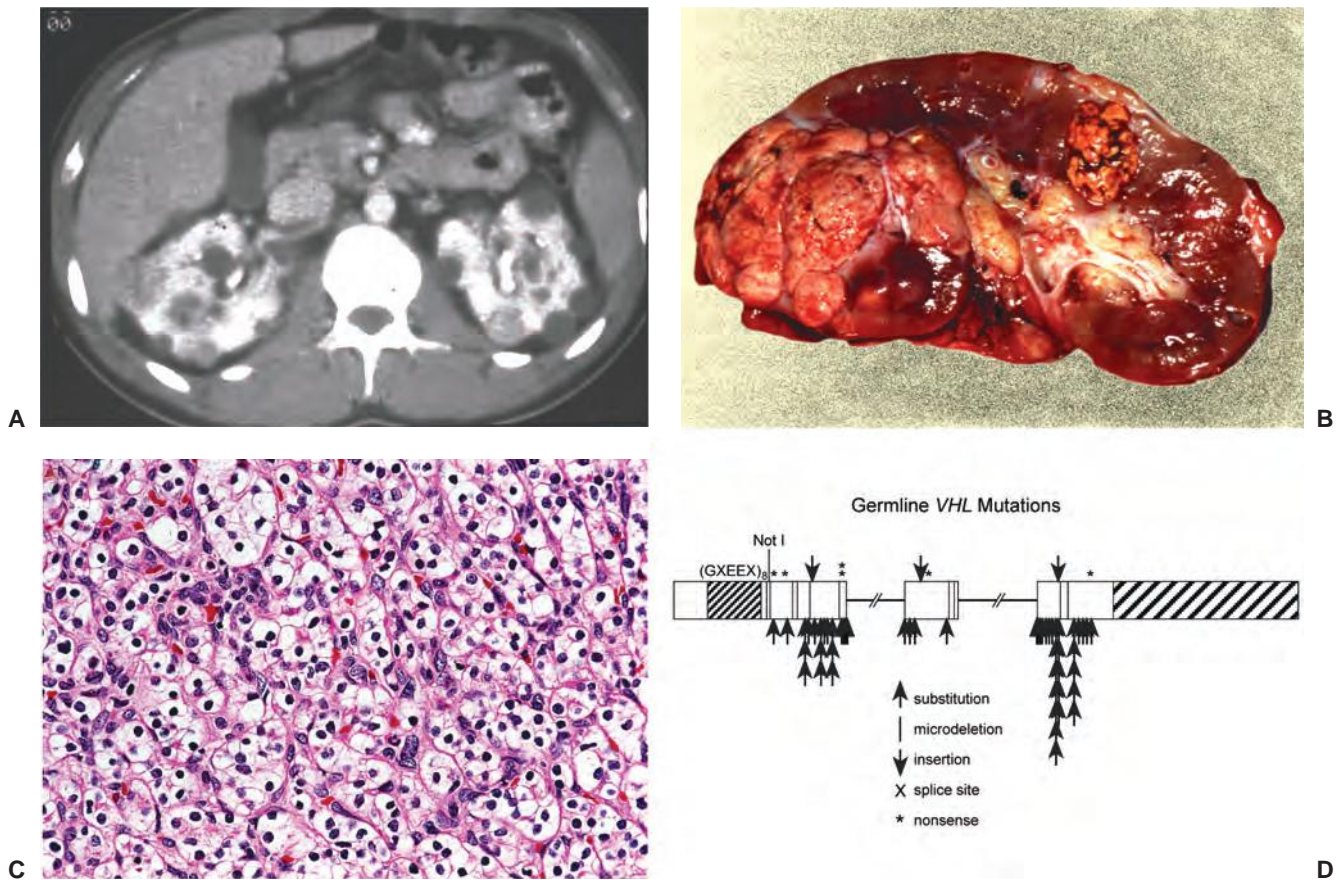

Figure 63.3 The von Hippel-Lindau (*VHL*) gene is responsible for the inherited form of clear cell renal cell carcinoma (ccRCC): VHL syndrome. **(A)** Axial computed tomography image showing multifocal and bilateral renal tumors and cysts. **(B)** Gross image of nephrectomy specimen showing typical yellow-gold appearance of ccRCC present in multiple portions of this kidney from a patient with VHL. **(C)** Histologic appearance of ccRCC, showing the clearing of the cytoplasm around the darker nuclei typical of these “clear cells.” **(D)** Structure of the *VHL* gene with sites of point mutations and truncations indicated. (Table 63.4). The involvement of an urologist with expertise in the management of RCC is essential for selection of the optimal strategy based on the individual features of each patient and tumor.

Radical Nephrectomy for Renal Cell Carcinoma

The objective of surgical therapy for RCC is to excise all of the cancer with an adequate surgical margin. Simple nephrectomy was practiced for many decades, but was replaced by RN when Robson and colleagues (1969) established this procedure as the “gold standard” approach for localized RCC.⁶⁸ “RN” as currently practiced may be better termed “total nephrectomy,” as it often omits several of the components of the original, “radical” nephrectomy, which always included extrafascial nephrectomy, adrenalectomy, and extended lymphadenectomy from the crus of the diaphragm to the aortic bifurcation. Perifascial dissection is still routinely practiced for larger tumors, as $\geq 25\%$ of these tumors extend into the perinephric fat.^{69,70} Removal of the ipsilateral adrenal gland is no longer recommended, unless there is suspicion of direct invasion of the gland by tumor or a radiographically or clinically suspicious adrenal tumor, because of the similar propensity of RCC to metastasize to the ipsilateral or contralateral adrenal gland.^{71–73} Finally, extended lymphadenectomy has been shown to be of no benefit for patients with clinically localized RCC and remains controversial for those with higher-risk disease.^{74–77}

RN is still a preferred option for many patients with localized RCC, such as those with very large tumors (most clinical T2

tumors) or the relatively limited subgroup of patients with clinical T1 tumors that are not amenable to nephron-sparing approaches.⁷⁸ The surgical approach for RN depends on the size and location of the tumor, as well as the patient’s habitus and medical/surgical history. For locally advanced disease and/or bulky lymphadenopathy, an open surgical approach using either an extended subcostal, midline, or thoracoabdominal incision is generally used.⁷⁹

Current minimally invasive approaches allow all of the essential steps of RN to be performed, with the associated benefits of shorter convalescence and reduced morbidity.^{80–83} Laparoscopic RN is now established as a preferred approach for moderate to large volume tumors (≤ 10 cm to 12 cm), without invasion of adjacent organs, with limited (or no) venous involvement, and having manageable (or no) lymphadenopathy. Therefore, a minimally invasive approach is suitable for most patients with renal tumors, even including some patients with features previously thought to mandate open RN.

On the other hand, RN has fallen out of favor for smaller renal tumors due to concerns about chronic kidney disease (CKD), and it should only be performed when necessary in this population.^{53,58,78,84} Several studies have shown an increased risk of CKD on longitudinal follow-up after RN.^{58,85,86} Huang et al. first reported that 26% of patient populations with a small renal mass, normal opposite kidney, and “normal” serum creatinine had pre-existing grade 3 CKD (estimated glomerular filtration rate [eGFR] < 60 ml/min per 1.73 m²). After surgery, stage 3b or higher CKD (eGFR < 45 ml/min per 1.73 m²) was more common after RN than PN (36% versus 5%, $p < 0.001$). CKD has been proven to lead to increased rates of cardiovascular events and death, with

Figure 63.4 Partial nephrectomy. The intention of kidney-sparing surgery, or “nephron-sparing surgery,” is to achieve complete local resection of the tumor while leaving as much functioning parenchyma in the involved kidney as possible. An assessment of volume preservation can be made by accounting for both the amount of parenchyma replaced by tumor and the adjacent uninvolved parenchyma removed or devascularized during the procedure.⁶¹ The amount of volume preservation and the quality of the functioning renal remnant are the most important determinants of renal function after renal surgery. Partial nephrectomy and other kidney-sparing alternatives provide definite renal functional benefits that must be weighed against the potential for increased risk of cancer recurrence, when compared with radical nephrectomy.²⁸⁷ (Artwork courtesy of Kristen Tobert.)

proportionally greater impact with higher CKD stage (and lower GFR). For example, in a population-based study of >1 million subjects, the relative death rates were 1.2, 1.8, 3.2, and 5.9 for eGFR (ml/min per 1.73 m²) of 45 to 60, 30 to 45, 15 to 30, and <15, respectively, even after controlling for hypertension, diabetes, and other potential confounding factors.⁸⁷ Coupled with the biologic heterogeneity of small renal masses, many of which will never lead to compromised survival, the potential negative consequences of RN on renal function have highlighted the importance of nephron-sparing approaches.^{53,58,72,88–90}

Partial Nephrectomy for Renal Cell Carcinoma

Kidney-sparing surgery for renal tumors was first described by Czerny in 1890; however, significant morbidity limited its use for the next half century.⁹¹ Vermooten (1950) revisited the concept of local excision with a margin of normal parenchyma for encapsulated and peripherally located renal tumors.⁹² The use of PN for RCC has subsequently been stimulated by experience with renal vascular surgery for other conditions, advances in renal imaging, growing numbers of incidentally discovered small renal masses, greater appreciation of the deleterious effects of CKD, introduction of minimally invasive techniques, and encouraging long-term survival in patients undergoing this form of treatment during the

last 50 years.^{93–95} Kidney-sparing surgery entails complete local resection of the tumor while leaving the largest possible amount of normal functioning parenchyma in the involved kidney (see Fig. 63.4).

Initially described for patients with an “absolute” indication for kidney-sparing surgery or for the “elective” indication of a small renal tumor in the setting of a normal contralateral kidney, PN is now strongly considered whenever preservation of renal function is potentially important. Common indications include conditions that pose a threat to future renal function, such as hypertension, diabetes mellitus, peripheral or coronary artery disease, or nephrolithiasis, and patients with baseline CKD, an abnormal contralateral kidney, or those with multifocal or familial RCC.^{96,97} PN is generally considered feasible for the vast majority of localized renal masses <5 cm in size and often for tumors ≥7 cm by those with expertise with kidney-sparing surgery.^{98–101} Particularly for those with a strong rationale for nephron-sparing surgery, PN can even be performed for tumors that deeply invest the renal vascular structures or with limited venous thrombus, but such procedures clearly carry higher perioperative morbidity.^{95,102} Local recurrence rates after PN for imperative indications have averaged 3% to 5% or higher in historical series.¹⁰³ The decision to perform a PN in such circumstances should be individualized, weighing the potential increased technical and oncologic risks of such an operation with the renal functional consequences of RN (see Fig. 63.4).

PN clearly leads to improved functional outcomes, when compared with RN, even for complicated situations.^{104,105} Temporary or permanent renal replacement therapy has been reported to be necessary in <5% of patients undergoing PN in a solitary kidney and is rarely needed for patients with a functioning contralateral kidney.^{106,107} In fact, the vast majority of patients will avoid permanent dialysis, even following multiple surgeries for multiple tumors in both kidneys, so long as at least 30% of a well-functioning remnant kidney is preserved.⁹⁵ For situations in which PN is deemed impossible, RN with ensuing hemodialysis is sometimes necessary, but presurgical therapy with a tyrosine-kinase inhibitor is an alternative approach that has proven successful in some patients.^{108–111}

For patients with clinical T1 renal masses, local recurrence rates are 1% to 2% after PN and most commonly located distant from the initial resection. Cancer-free survival is achieved in well above 90% of patients.¹⁰⁴ The contralateral kidney is also at risk for metachronous disease, which also occurs in 1% to 2% of patients, even with contemporary imaging modalities. This provides further rationale to avoid unnecessary RN for tumors amenable to nephron-sparing surgery. The goal of PN is resection of all grossly appreciated tumor with negative microscopic surgical margins; this is generally performed with a thin rim of normal parenchyma based on prior literature indicating that margin width is immaterial.^{67,112–117} Some centers now routinely perform enucleation of renal tumors with excellent oncologic outcomes, although enthusiasm for more widespread use of this approach has been tempered by the somewhat higher recurrence rate among patients with RCC with positive margins and the propensity of some RCC subtypes to invade the pseudocapsule that is generally present.

Within the last decade, substantial progress has been made with minimally invasive PN, which is now the most commonly performed procedure for small renal masses. Laparoscopic PN, with or without robotic assistance, is performed according to the same principles as open PN. Margin status and oncologic outcomes with laparoscopic and open PN appear equivalent in series of patients in which patients were selected appropriately for each of these approaches.^{101,118} Although early to intermediate experience with laparoscopic PN suggested increased urologic complications compared with open RN,¹¹⁹ subsequent experience with pure laparoscopic PN and more prevalent use of robotic PN have substantially reduced perioperative morbidity.^{104,120–125} Tumor complexity remains a major predictor for intraoperative and postoperative complications, regardless of surgical approach, and open PN should be considered for particularly challenging situations.¹²⁶

TABLE 63.4

Treatments for Localized Renal Cell Carcinoma

	Advantages	Disadvantages	Main Indications
ORN	Traditional surgical approach for renal cancer, effective in removing tumor with surrounding structures and lymph nodes when indicated	Morbidity of surgical incision (flank, subcostal, midline, thoracoabdominal) Renal functional implications of removing entire kidney (average 35% decrease in GFR)	Large tumor (>12 cm) Locally advanced tumor Bulky adenopathy
MIRN	Reproducible and effective surgery for most localized renal tumors Minimally invasive surgery, with decreased pain, morbidity and convalescence compared to ORN	Many tumors up to 7 cm can be treated with PN Renal functional implications of removing entire kidney (average 35% decrease in GFR)	Medium to large tumor (up to 10 to 12 cm) High tumor complexity
OPN	Oncologic outcomes appear similar to RN, although selection biases limit this conclusion Maximizes renal functional preservation when performed with precise tumor excision and judicious use of regional hypothermia	Morbidity of flank incision (bulge, longer recovery) Potential for local recurrence due to incomplete excision or de novo tumors in the renal remnant	Small to medium tumors (up to 7 cm and occasionally larger) Moderate to high-complexity tumors
MIPN	Kidney-sparing surgery, with preservation of renal function when warm ischemia kept to limited duration (<20 to 25 min) Minimally invasive surgery, with decreased pain, morbidity, and convalescence compared to OPN	Higher complication rate for high complexity tumors and in less-experienced hands Positive surgical margins and local recurrence rates may be higher in such situations	Small renal masses (up to 5 cm and occasionally larger) Low to moderate (and selected high) complexity tumors
TA	Kidney-sparing approach, with renal functional benefits versus RN Can be performed outside of OR (percutaneous) or with minimally invasive approach (laparoscopic) For small (<3 cm) tumors, provides comparable control of metastasis to PN and RN	Relatively high rate of local failure Imprecision of histopathologic diagnosis Increased and challenging radiographic follow-up	Prior ipsilateral surgery for renal tumor Poorer surgical candidates unwilling to undergo surveillance
AS	Least invasive and kidney-sparing of all strategies Most SRMs have limited oncologic potential and can be safely managed with initial short interval follow-up imaging Intensity of surveillance can be tailored to patient and tumor characteristics	Tumor remains in place and untreated Oncologic nature of tumor unknown (without biopsy)	Poor surgical candidates Limited life expectancy

ORN, open radical nephrectomy; GFR, glomerular filtration rate; MIRN, minimally invasive radical nephrectomy; OPN, open partial nephrectomy; RN, radical nephrectomy; MIPN, minimally invasive partial nephrectomy; TA, thermal ablation; OR, operating room; PN, partial nephrectomy; AS, active surveillance; SRM, small renal mass.

Thermal Ablation of Renal Cell Carcinoma

TA, including renal cryosurgery and radiofrequency ablation (RFA) have emerged as alternative kidney-sparing treatments for patients with small (<3 cm) renal tumors.^{127,128} Both can be administered percutaneously or with laparoscopic exposure and thus offer the potential for reduced morbidity and more rapid recovery compared with extirpative approaches.^{128,129} In general, the long-term efficacy of TA has not been well established when compared to surgical excision, and current data suggest that the local recurrence rates are somewhat higher than that reported with extirpative approaches.^{55,63} Another concern has been the lack of accurate histologic and pathologic information obtained with these modalities because the treated lesion is left in situ.

The ideal candidates for TA are patients with advanced age and/or significant comorbidities who prefer a proactive approach (over surveillance), but are not optimal candidates for conventional surgery, patients with local recurrence after previous kidney-sparing surgery, and patients with hereditary renal cancer who present with multifocal lesions for which multiple PNs might be cumbersome.⁵⁵ Patient preference must also be considered as some patients not fitting these criteria may select TA after balanced counseling about the current status of these modalities.^{130,131} Tumor size is an important factor in patient selection because the current technology

does not allow for reliable treatment of lesions >4 cm and success rates appear to be highest for tumors <2.5 cm to 3 cm.¹³²⁻¹³⁵

Clinical experience and follow-up of patients after renal cryosurgery suggests successful local control in about 90% of patients, although many studies provide limited and often incomplete follow-up.¹³⁶⁻¹⁴⁰ Diagnosis of local recurrence after TA can be challenging because evolving fibrosis within the tumor bed can be difficult to differentiate from residual cancer. In general, central or nodular enhancement within the tumor bed on extended follow-up has been considered diagnostic of local recurrence and the clinical experience with cryoablation has thus far supported this.^{141,142} Other findings that suggest local recurrence include failure of the treated lesion to regress over time, a progressive increase in size of an ablated neoplasm, new nodularity in or around the treated zone, or satellite or port site lesions.¹⁴³ If these features are found, biopsy and possible retreatment should be considered. The AUA guidelines for surveillance after TA include cross-sectional scanning (computed tomography or MRI) with and without intravenous contrast at 3 and 6 months following ablative therapy and annually with chest X-ray for 5 years thereafter.¹⁴³

More mature data from a limited number of studies now provide encouraging outcomes for smaller tumors, particularly those <3 cm, yet the cumulative experience continues to suggest that local control after cryoablative therapy remains suboptimal when

compared to surgical excision.^{55,138} The 5-year local recurrence rates in two series were 8% to 9%,^{52,144} which is significantly higher than the 1% to 2% consistently reported with surgical excision of analogous small renal masses.⁵³ Other concerns with TA relate to surgical salvage and potential morbidity. Most local recurrences can be salvaged with repeat ablation, but some patients with progressive disease eventually require surgical extirpation. Nguyen and colleagues (2008b) have shown that PN and minimally invasive approaches are occasionally precluded in this setting due to the extensive fibrotic reaction induced by TA.⁷⁸ As expected, the incidence of treatment failure or complications after TA correlates with tumor size and complexity.¹⁴⁵

The experience with RFA has been even more variable, likely related to surgeon experience, the availability of different platforms for the procedure, and inability to monitor treatment progress.¹²⁸ Local control after RFA is estimated to be 80% to 90%, although the definitions of local recurrence within the literature have been inconsistent.^{53,55} Although loss of enhancement on cross-sectional imaging within the lesion has generally been accepted as an indicator of success, viable cancer cells have been detected at biopsy of the tumor bed even in the absence of enhancement on the MRI 6 months after treatment.¹⁴² The issue of potential false-negative and false-positive imaging findings after TA remains a concern, and more strict definitions of local control after TA were recently advocated by an AUA guidelines panel.^{143,146} The technology for RFA continues to improve with most contemporary series reporting relatively low rates of local recurrence. Some patients require repeat treatments to achieve local control, which is an infrequent event with cryoablation and rarely required with conventional surgical treatments for localized RCC.¹²⁸ One recent series documented local control in 91% of 179 patients with biopsy proven RCC at median follow-up of 27 months.¹³⁵ Some RFA series report even more encouraging results, particularly for tumors <3 cm diameter,¹³² but others have reported 5-year local recurrence rates as high as 39%.¹⁴⁷

Complications from ablation are uncommon, but have included acute renal failure, stricture of the ureteropelvic junction, necrotizing pancreatitis, and lumbar radiculopathy; therefore, careful and judicious selection of patients is essential.¹²⁸ Direct comparisons between cryoablation and RFA are inevitable, but perhaps unfair because RFA is earlier in its development and recent reports suggest great promise.^{128,132} Other new technologies, such as high-intensity focused ultrasound and frameless, image-guided radiosurgical treatments (CyberKnife), are also under development and may allow extracorporeal treatment of small renal tumors in the future.¹⁴⁸⁻¹⁵⁰ However, at present cell kill with these modalities is not sufficiently reliable and they should still be considered developmental.¹⁵¹

Active Surveillance of Clinically Localized Renal Cell Carcinoma

The concept of overdiagnosis and overtreatment of kidney cancers is a relatively new concept. The risks and consequences associated with unnecessary treatment of low-risk RCC are an unintentional, yet underappreciated harm associated with incidental detection of these tumors. While early detection leads to “cure,” lead time biases in reported surgical series and the growing recognition that some localized renal tumors exhibit an indolent natural history have challenged the “find it, excise it” practice pattern. As the data emerge, AS remains a rational therapeutic option, particularly in the elderly or infirm where competing health, surgical, or renal functional risks may exceed that of the tumor’s biology.^{152,153}

Objectifying and comparing the risks of treatment (excision/ablation) versus AS remains difficult as the data upon which competing risks models are based remain largely retrospective and incomplete.²⁸ Nonetheless, data have emerged to suggest

that radiographically localized small renal masses, most of which are RCC,^{154,152} exhibit slow linear/volumetric growth (0.3 cm/year on average) with a low metastatic potential (1.1% to 1.4%) over the first 24 to 36 months following diagnosis.^{154,152}

Moreover, in patients with localized small renal tumors at diagnosis, the risk of metastases appears to be related to both the size of the primary tumor and perhaps more importantly the growth kinetics of the lesion.¹⁵⁵ Interestingly, as many as 20% to 30% of small renal tumors exhibit zero radiographic growth over the initial 24 months following diagnosis.⁵⁵ Given these data, the practice of AS with delayed intervention informed by an objective assessment of risk in the elderly, infirm, and/or well-informed is emerging.¹⁵⁶ This practice is a calculated risk accepted by the patient and managed by the physician. Percutaneous biopsy and emerging biologic and genetic markers will continue to improve the decision-making process. In the meantime, AS remains a viable option for highly motivated patients and highly engaged physicians.

Follow-Up for Localized Renal Cell Carcinoma

Follow-up for cancer survivors focuses broadly on early detection of cancer recurrence. With earlier diagnosis of many cancers and a longer length of life after diagnosis and treatment, an increasing number of survivors remain under the care of cancer specialists and primary care physicians. Wide variations in recommended practice have led to the development of guidelines by various organizations. The AUA released guidelines for follow-up of clinically localized RCC in 2013 that reflect a consistent approach that also takes into account the heterogeneity of the population of cancer survivors (Table 63.5).¹⁴³ Clinicians should be aware that in managing adult cancer survivors they are not only looking for RCC recurrence, but also monitoring for secondary malignancy and the effects of cancer treatment, implementing therapies to prevent recurrences or new tumors, understanding the consequences of cancer and its treatment effects, and coordinating the overall care between cancer specialists and the primary care physician to meet each individual’s needs.

TREATMENT OF LOCALLY ADVANCED RENAL CELL CARCINOMA

Surgery for Tumor Thrombus in the Inferior Vena Cava

Renal tumors are unique in their ability to form tumor thrombi that can propagate from the ipsilateral renal vein into the IVC and extend as far as the patient’s right atrium. Approximately 4% to 10% of patients who present with renal masses will have a concomitant tumor thrombus. The level of tumor thrombus is classified as level 0 (thrombus limited to the renal vein), level I (thrombus extending into the inferior vena cava ≤ 2 cm above the renal vein), level II (thrombus extending into the inferior vena cava >2 cm above the renal vein, but below the hepatic veins), level III (thrombus extending into the inferior vena cava to or above the level of the hepatic veins, but still remaining below the diaphragm), and level IV (thrombus extending into the inferior vena cava and above the level of the diaphragm) (Fig. 63.5). A tumor thrombus should be suspected in patients with a renal tumor who also have new onset lower extremity edema, an isolated right-sided varicocele or one that does not collapse with recumbency, dilated superficial abdominal veins, proteinuria, pulmonary embolism, right atrial mass, or nonfunction of the involved kidney.

Five-year cancer-specific survival for patients with RCC and venous extension ranges from 45% to 70%, and surgical therapy in the form of RN and IVC thrombectomy can be curative. Interestingly, many patients with vena cava extension will present

TABLE 63.5

Guidelines for Follow-Up of Clinically Localized Renal Cell Carcinoma

Follow-up Measure	Recommendation
Physical exam and history	History and physical examination directed at detecting signs and symptoms of metastatic spread or local progression
Laboratory testing	Basic laboratory testing including blood urea nitrogen/creatinine, urinalysis and estimated glomerular filtration rate for all patients Progressive renal insufficiency should prompt nephrology referral Complete blood count, lactate dehydrogenase, liver function tests, alkaline phosphatase, and serum calcium per discretion of the physician
Abdominal imaging	Obtain a baseline abdominal scan (CT or magnetic resonance imaging) within 3 to 6 mo following surgery, and periodically thereafter based on individual risk factors (e.g., every 6 mo for 3 y for moderate to high-risk RCC) Perform site-specific imaging as symptoms warrant Imaging beyond 5 y may be performed at the discretion of the clinician
Chest imaging	Low-risk RCC: Chest X-ray annually for 3 y and only as clinically indicated beyond that time period Moderate to high-risk RCC: baseline chest CT 3 to 6 mo after surgery with continued imaging (chest X-ray or CT) every 6 mo for at least 3 y Imaging beyond 5 y is optional and should be based on individual patient characteristic and tumor risk factors
Bone scan	Elevated alkaline phosphatase, clinical symptoms such as bone pain, and/or radiographic findings suggestive of a bony neoplasm should prompt a bone scan Bone scan should not be performed in the absence of these signs and symptoms
Central nervous system imaging	Acute neurologic signs should lead to prompt neurologic cross-sectional imaging of the head or spine based on localized symptoms

CT, computed tomography; RCC, renal cell carcinoma.

without metastatic disease.^{157,158} The prognostic significance of IVC thrombus level has been controversial. Most studies suggest that the incidence of locoregional or systemic progression is higher in patients with level III-IV IVC thrombus, which may account for the reduced survival reported in this subgroup in some series.^{159–162} Other series have shown that any IVC involvement is worse than renal vein involvement without distinction with regard to IVC level; in these series, other factors, such as nodal or metastatic involvement and tumor grade, have more impact on overall survival (OS).^{163,164} Despite this debate, patients with any tumor thrombus

level can be cured with surgical resection, even level IV, in the absence of metastases and other adverse features.^{165–168}

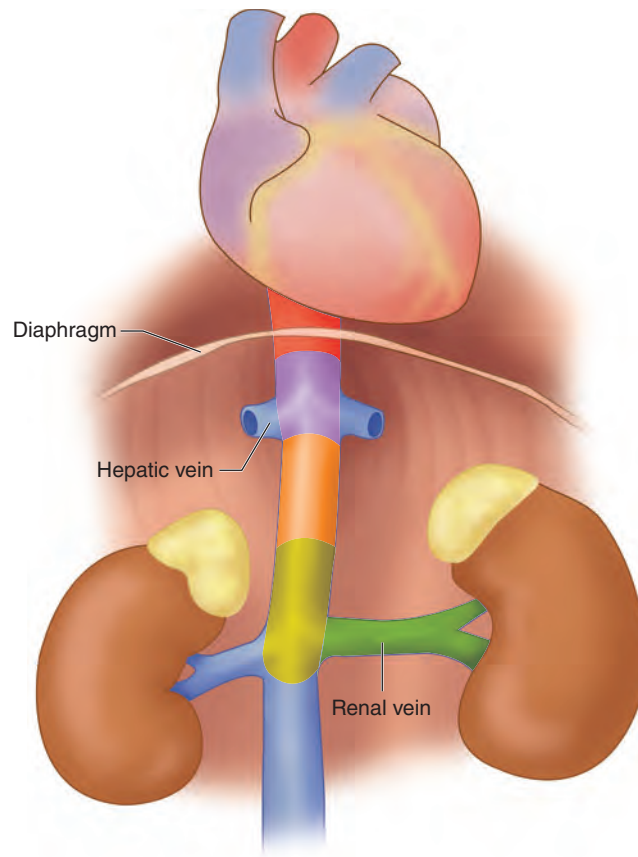

More recent series have re-evaluated the clinical variables predictive of survival after surgery for patients with tumor thrombi. In a single institutional series of 99 patients, median survival for patients with level I/II tumor thrombus was 6.6 years compared to 1.4 years for patients with level III/IV tumor thrombi. Higher level of tumor thrombus (III/IV versus I/II), hazard ratio [HR] = 1.84 95% confidence interval [CI] = 1.03 to 3.30, $p = 0.041$) and the presence of metastatic disease at the time of surgery (HR = 2.97, 95% CI = 1.65 to 5.36, $p < 0.001$) both portended a worse OS on multivariate analysis.¹⁶⁹ Other investigators have examined the impact of tumor histology on clinical and pathologic outcomes in patients with venous tumor extension. Authors at the Mayo Clinic found that patients with non-clear cell histology presented with a significantly larger tumor size, greater rate of lymph node disease, higher nuclear grade, and more frequent sarcomatoid differentiation.¹⁷⁰ As a result of these clinical and pathologic variables, these patients had a considerably worse 5-year cancer-specific survival as compared with patients with clear cell histology ($p = 0.03$).¹⁷⁰ Similarly, a recent international multi-institutional retrospective study analyzed the role of tumor histology on survival in patients undergoing RN and caval thrombectomy. In this series of 1,774 patients, the overall 5-year cancer-specific survival was 53.4%.¹⁷¹ In this series' multivariable analysis, papillary histology (HR = 1.62, 95% CI = 1.01 to 2.61, $p < 0.05$), fat invasion (HR = 1.49, 95% CI = 1.10 to 2.03, $p < 0.01$), and thrombus level ($p < 0.01$) were all independent predictors of a poor cancer-specific survival.¹⁷¹ In contrast to the Mayo series, when the authors restricted their analysis to only NOM0 patients, thrombus level and papillary histology were still significantly associated with a decreased cancer-specific survival.^{170,171}

Surgery remains an integral part in the treatment paradigm for patients with tumor venous extension because of the sequelae of such vascular involvement. The surgical approach and technique to treat these challenging tumors are tailored to the level of IVC thrombus, but uniformly begin with careful mobilization of the kidney and early ligation of the arterial blood supply.^{164,172,173} With an increasing tumor thrombus level, more advanced surgical techniques are required for vasculature control and complete tumor extirpation, including veno-venous bypass and cardiopulmonary bypass potentially with hypothermic circulatory arrest for some cases. Specifically for level III and level IV thrombi, a multidisciplinary surgical team is often required for advanced surgical maneuvers, including a liver surgeon to aid in mobilization of the liver and exposure of the intrahepatic IVC and a vascular and/or cardiac surgeon if bypass is required.

Despite the surgical ability to resect these tumor thrombi, perioperative mortality rates associated with RN and IVC thrombectomy have been reported to be as high as 5% to 10% in some series, depending on patient comorbidities and tumor characteristics.^{164,166} Although there may be a palliative role for surgery in some patients with metastasis who experience severe disability from intractable edema, ascites, cardiac dysfunction, or associated local symptoms such as abdominal pain and hematuria, most such patients will not benefit due to risk of perioperative morbidity and limited life expectancy.^{174,175}

Lymphadenectomy

The need for extensive lymphadenectomy in patients undergoing RN remains a subject of debate. Despite the fact that multiple prior studies have shown a survival benefit with a lymph node dissection performed at the time of nephrectomy,^{75,176,177} a recent randomized trial failed to show a distinct advantage.⁷⁴ Although this trial represents level I evidence, its generalizability is limited since the trial included many patients at low risk for nodal metastasis (81% of patients had grade 1 or 2 tumors and 72% had organ-confined

Prognostic and surgical staging systems of IVC tumor thrombus

Anatomic landmark	Staging systems				
	TNM	Neves	Novick	Hinman	Robson
RV	T3b	0	I	I	IIIa
IVC <2 cm above RV		I	II		
IVC >2 cm above RV and below hepatic veins		II			
IVC above hepatic veins and below diaphragm		III	III	II	
IVC above diaphragm	T3c	IV	IV	III	

Figure 63.5 Classification of renal cell carcinoma venous tumor thrombi. Level 0 (green): Thrombus within main renal vein (RV) or its branches and not reaching into the inferior vena cava (IVC). Level I (yellow): IVC thrombus is present within the IVC, <2 cm above renal vein. Level II (orange): IVC thrombus extends along the IVC, but not to the level of the main hepatic veins. Level III (purple): IVC thrombus extends within the IVC above the level of the main hepatic veins, but below the diaphragm. Level IV (red): IVC thrombus extends above the diaphragm, near to or into the right atrium and occasionally beyond. TNM, tumor, node, metastasis. disease).⁷⁴ Furthermore, in the entire cohort, lymph node metastases were present in only 4% of patients undergoing complete lymph node dissection.⁷⁴ Based on this trial, a compelling argument for lymph node dissection in patients with clinically localized RCC cannot be supported.

Of greater impact is the study from Blute and colleagues¹⁶⁴ who elucidated pathologic features associated with increased risk for nodal metastases: tumor grade (grade 3 or 4), presence of a sarcomatoid component, tumor size ≥ 10 cm, tumor stage pT3 or pT4, and histologic tumor necrosis. Based on this study and a subsequent prospective evaluation of this approach, patients with two or more of these risk factors should be considered for extensive lymph node dissection incorporating the ipsilateral renal hilar

region, the ipsilateral great vessel, and the interaortocaval region. This dissection should extend from the crus of the diaphragm to the common iliac artery. In a retrospective study, 45% of patients had positive lymph nodes outside of the renal hilar region, mandating a broader template.¹⁷⁷ Finally, a recently published retrospective study of 1,983 patients treated for RCC assessed the factors predictive of lymph node invasion and/or progression. In this study, the overall prevalence of lymph node invasion was 6.1% and the clinical factors that were independently predictive of lymph node involvement were tumor stage (T3–T4), clinical nodal status, the presence of metastatic disease, and tumor size as a continuous variable.¹⁷⁸ Using these variables, the authors created a nomogram that calculates a patient's probability of having lymph

node disease at the time of nephrectomy or in disease follow-up.¹⁷⁸ It appears fair to conclude that a lymph node dissection is not routinely needed for organ-confined disease; however, the presence of multiple adverse pathologic features (e.g., large tumor size, locally advanced disease, etc.) seems to favor performing a lymph node dissection that is more extensive than simply the hilar region.

ADJUVANT THERAPY FOR RENAL CELL CARCINOMA

Although a significant proportion of patients can be considered to be cured or in remission after surgical treatment for nonmetastatic RCC, distant metastases are detected in 20% to 35% and local recurrence in 2% to 5% of patients.^{54,94} Patients with locally advanced RCC and other high-risk features are at greater risk of recurrence and various predictive tools can be used to provide an individualized estimate.⁵⁴ Despite the significant likelihood of recurrence in patients with poor-risk features, no therapy has ever been shown to be of benefit in the adjuvant setting. Prior trials have evaluated hormone therapy, radiotherapy, immunotherapy, and tumor vaccines, all with essentially negative results. Based on the significant antitumor activity of targeted molecular therapies in advanced RCC, a number of randomized trials evaluating the ability of these agents to prevent metastasis have completed enrollment and results of these trials can be expected as early as 2015 (Table 63.6).

SURGICAL MANAGEMENT OF ADVANCED RENAL CELL CARCINOMA

Cytoreductive Nephrectomy

Approximately 30% to 40% of patients will present with metastatic or advanced RCC.¹⁷⁹ For these patients, multimodal therapy, which includes surgery, has produced improved progression-free survival (PFS) and OS. The National Comprehensive Cancer

Network Guidelines for kidney cancer list cytoreductive nephrectomy (CN) with or without metastasectomy prior to systemic treatment as the primary treatment option for patients with stage IV RCC.¹⁸⁰ The data supporting this recommendation come from three randomized trials demonstrating a survival benefit for patients who received systemic immunotherapy with interferon (IFN)-alpha after surgical removal of the primary tumor.¹⁸¹⁻¹⁸³ Flanagan et al.¹⁸¹ found the median survival of 120 patients assigned to surgery followed by IFN-alpha to be 11.1 months compared to 8.1 months in 121 patients assigned to IFN-alpha alone ($p = 0.05$). Similarly, Mickisch et al.¹⁸³ found time to progression (5 months versus 3 months) and median duration of survival to be better in patients randomized to surgery plus IFN-alpha compared to those randomized to IFN-alpha alone. Combining the survival data from all these trials resulted in a median survival of 13.6 months versus 7.8 months for patients undergoing surgery in addition to IFN-alpha as compared to IFN-alpha alone.^{181,183-185}

More recent data accounting for the current use of targeted therapies as first-line systemic therapy for patients with metastatic RCC have confirmed the survival advantage associated with CN. In one retrospective study, patients ($n = 201$) who underwent CN had an independent statistically significant survival advantage as compared to patients ($n = 113$) who did not (HR = 0.68; 95% CI = 0.46 to 0.99, $p = 0.04$).¹⁸⁶ This survival advantage was present even when adjusting for contemporary adverse prognostic risk factors (e.g., performance status, time from diagnosis to therapy initiation, anemia, hypercalcemia, neutrophilia, and thrombocytosis).¹⁸⁷ Despite these promising results, other studies have shown that CN may not confer a survival advantage in patients with non-clear cell histology, especially those with sarcomatoid features.^{172,188,189} Fortunately, a prospective study evaluating the benefit of surgery in combination with sunitinib versus sunitinib alone is currently ongoing in patients with metastatic RCC.

Although the use of laparoscopic/minimally invasive techniques in patients with advanced disease can potentially provide a less invasive and less morbid method for cytoreduction as preparation for administration of systemic therapies, CN is still not without risk, and surgical risk assessment needs to be considered preoperatively. According to prior reports, patients that are most

Source: Zisman A, Pantuck AJ, Chao DH, et al. Renal cell carcinoma with tumor thrombus: is cytoreductive nephrectomy for advanced disease associated with an increased complication rate? *J Urol* 2002;168:962-967.

likely to benefit from CN are those patients with lung-only metastatic disease, good prognostic features as defined by Motzer (or other) criteria, and a good performance status.^{175,190} Conversely, predictors of short survival for patients with advanced RCC include an elevated serum lactate dehydrogenase (LDH; >1.5 times upper limit of normal), a hemoglobin level <lower limit of normal, a corrected serum calcium level >10 mg/dl, an interval of <1 year from original diagnosis to the start of systemic therapy, a Karnofsky performance score ≤70, and two or more sites of organ metastasis.¹⁹¹ However, the challenge associated with these risk criteria is that they mostly account for the risk associated with the disease and do not consider the perioperative risk to the patient, which is not insignificant.

For example, Abdollah et al.¹⁹² identified 17,688 patients within the Florida Inpatient Database that underwent nephrectomy between the years 1999 to 2008. They identified 1,063 (6%) patients who underwent a CN and found that these patients were more likely to have a longer length of stay (8.4 versus 5.7 days, $p < 0.001$), a secondary surgical procedure (28.3% versus 10%, $p < 0.001$), an in-hospital mortality (2.4% versus 0.9%, $p < 0.001$), and a postoperative complication (26.5% versus 18.9%, $p < 0.001$). In this report, increasing age was predictive of increasing in-hospital mortality and complications for patients undergoing CN. A similar analysis was conducted by Trinh et al.¹⁹³ using the Nationwide Inpatient Sample registry. Thirty one percent of the study population ($n = 16,285$) experienced a perioperative complication, and patients ≥75 years old who had a comorbidity score ≥3 were more likely to experience a complication after CN (both $p < 0.001$).¹⁹³ Of the patients ($n = 4,974$) that experienced an adverse event, 5% ($n = 245$ patients) died during their hospitalization.¹⁹³ Finally, it is worth noting that despite the survival advantage garnered from a CN followed by targeted therapy, it is not universally received. In a single institutional study from the Fox Chase Cancer Center, only 69.5% of patients actually received systemic therapy after surgery.¹⁹⁴ The most common reason in this study for patients not to receive systemic therapy was rapid disease progression, which occurred in 30% of patients. Also, there were eight perioperative deaths, accounting for 19% of patients who did not receive systemic treatment.¹⁹⁴

In summary, CN offers patients with metastatic RCC a survival advantage and the National Comprehensive Cancer Network Guidelines recommend a CN for patients with an Eastern Cooperative Oncology Group performance status <2 who have no evidence of brain metastasis.¹⁸⁰ Despite these recommendations, recent data has shown that surgical risk associated with CN is not insignificant, especially in the elderly and comorbid, and should be weighed against the patient's disease biology (presence of poor-risk disease) before reflexively proceeding with surgery.

Surgical Management of Recurrent and Metastatic Disease

Approximately one-third of patients initially diagnosed with RCC will present with metastatic disease.¹⁷⁹ An additional 40% of patients that present with localized disease will ultimately develop metastatic disease.^{179,195} As these statistics illustrate, the biology of RCC is unique and variable and as such the treatment of patients with metastatic RCC is as well. In patients with diffuse metastatic disease, metastatectomy is not routinely used for therapeutic purposes. However, for the subset of patients who either present with or develop low-volume, radiographically solitary, or limited metastases, whether it be synchronous or metachronous, resection is often an integral part of the treatment paradigm and can confer a survival advantage.^{180,196,197} Complete metastatectomy has been associated with a two-fold reduction in the risk of death from RCC.¹⁶²

Of the approximately 30% of patients with RCC who present with metastases, only 1.5% to 3.5% have a solitary metastasis.¹⁹⁸

Patients with a solitary synchronous metastatic lesion have decreased survival when compared with patients who develop metastasis after the primary tumor is removed.¹⁹⁹ Nevertheless, surgical resection of metastatic disease either alone or in combination with immunotherapy/targeted therapy has been shown to be curative or to confer a survival advantage compared to patients who did not undergo consolidative metastatectomy. However, these data must be interpreted in the context that only a small subset of patients will be optimal candidates for surgical extirpation of metastatic lesions. In a large series from the Mayo Clinic, 887 patients were identified with multiple metastatic sites of disease from RCC who underwent surgical resection. Of this large cohort, only 125 (14%) patients underwent a complete resection of their metastatic disease, whereas 698 (78.7%) patients had died of RCC at a median of 1.2 years after the first occurrence of their metastatic disease.²⁰⁰ In this analysis, the authors demonstrated that complete surgical resection of metastatic disease, across all subgroups, was predictive of improved survival. For example, the median RCC specific and OS for patients who underwent complete metastatectomy were 4.8 and 4.0 years, respectively.²⁰⁰ Comparative RCC-specific and OS rates for patients where complete surgical resection was not achieved were 1.3 and 1.3 years, respectively. Also, patients experienced an improved survival if they underwent complete surgical resection regardless of metastatic sites (lung versus nonlung, $p < 0.001$), number of metastatic sites ($p < 0.001$), and timing of metastatic disease—synchronous ($p < 0.001$) and asynchronous ($p = 0.002$).²⁰⁰ Finally, on multivariate analysis, patients in whom surgery did not achieve a complete metastatectomy were almost three times more likely to die of RCC (HR = 2.91; 95% CI = 2.17 to 3.90, $p < 0.001$).²⁰⁰ In this series, approximately half of the patients (45.6%) received some form of systemic therapy during their treatment course and the receipt of systemic therapy was associated with a significant improvement in survival only in patients who did not undergo complete metastatectomy, highlighting the importance of surgery in the treatment of metastatic/recurrent RCC.²⁰⁰

In patients treated with immunotherapy, there are multiple retrospective series demonstrating that patients who underwent metastatectomy had better outcomes than those who did not undergo resection of metastatic sites. In these series, 24% to 100% of patients were disease free 1 to 4 years postsurgery.^{201–206} More recent data in patients who have received targeted therapies has shown similar results, albeit in small patient cohorts. In a retrospective, multi-institutional study, only 22 patients with metastatic RCC who underwent metastatectomy after targeted therapy were identified. At a median follow-up of 42 weeks after surgery, 50% of patients had experienced a tumor recurrence; however, only one patient died of RCC 105 weeks after surgery.²⁰⁷

Surgical management of recurrent and metastatic RCC plays an important role in the treatment paradigm of this group of patients and appears to confer a survival advantage in retrospective series. However, not all patients will ultimately be optimal surgical candidates and the ability to achieve a complete surgical resection is paramount in helping to guide preoperative surgical decision making.

SYSTEMIC THERAPY FOR ADVANCED RENAL CELL CARCINOMA

Prognostic Factors

Clinical characteristics have been extensively studied as potential prognostic factors in metastatic RCC. Performance status is a measure of overall well-being and is the most consistently reported factor associated with survival in advanced RCC, while other demographic features, such as age, gender, and race, are of limited value.^{208–211} Some studies have found the presence of

visceral (i.e., lung, liver, and adrenal), bone, and brain metastases to be associated with poor survival,^{208,211,212} whereas others have found no relationship between these sites and prognosis.^{210,213} A more reliable finding is the number of metastatic sites present, which provides a rough estimate of tumor burden. Most studies have found that patients with higher number of metastatic sites (more than two) are independently associated with at least two-fold greater probability of death. Similarly, patients with a short interval from initial RCC diagnosis to metastases have been found to have a worse outcome, likely as a reflection of faster-growing disease.^{209,211,214,215} Those with synchronous metastases have outcomes intermediate between those with metastases developing within 1 year of diagnosis and those with asynchronous metastases that develop later.²¹⁶ Investigators have evaluated the effects of several laboratory parameters in patients with advanced RCC. Erythrocyte sedimentation rate, C-reactive protein, hemoglobin, white blood cell, and platelet parameters have been evaluated. Elevated erythrocyte sedimentation rate and C-reactive protein were consistently found to be independent poor prognostic factors.^{64,214,217,218} Patients with thrombocytosis (defined as platelet counts >400,000/ μ L), another potential marker of inflammation, have been reported to have a negative impact on survival mostly in patients with localized RCC. Studies overall have been inconsistent in the metastatic setting, especially when other markers of inflammation were considered. Anemia has also consistently been found to be an independent prognostic factor for an adverse outcome. Patients with pretreatment hemoglobin below the lower limit of laboratory normal values were found to have twice the risk of death compared with patients with normal hemoglobin in several large studies.^{210,211} The mechanism of effect of such blood parameters is unknown—whether these markers reflect an underlying inflammatory disease and/or somehow contribute to the disease process itself is unclear. Other biochemical factors that have been implicated in RCC prognosis include pretreatment serum LDH and calcium (corrected for albumin), while serum alkaline phosphatase, creatinine, gamma glutamyltransferase, and triglycerides have not been found to have prognostic value. Corrected serum calcium >10 mg/dL and LDH >1.5 times the upper limit of normal have been associated with a two- to three-fold higher risk of death, respectively.^{210,211,214}

Prognostic Schema

Using the previously identified variables, investigators have combined these variables to stratify patients into “risk groups” to predict outcome. Such schema serve to aid in individual patient counseling, stratify patients for randomized clinical trial entry, and aid in interpretation of nonrandomized clinical trials (Table 63.7). The most commonly employed schema from Memorial Sloan-Kettering Cancer Center was developed from patients treated with IFN-based regimens.²¹⁹ This schema uses Eastern Cooperative Oncology Group performance status, anemia, LDH, corrected serum calcium, and time from diagnosis to metastatic disease to segregate patients into three risk groups. This schema is still widely used today despite the limited IFN use currently and has been shown to also segregate patients treated with newer agents. More recent efforts have developed prognostic variables and risk groups based on patients treated with targeted agents. This schema uses hemoglobin, corrected calcium, performance status, and time from diagnosis to treatment, but additionally neutrophil and platelet count.¹⁸⁷ Both Memorial Sloan-Kettering Cancer Center and Heng criteria are used to describe patient populations treated in the targeted therapy era.

Predictive Markers

With the shift in systemic therapy for RCC to molecularly targeted agents, looking at the molecular characteristics of tumors

has occurred to identify additional prognostic factors. VHL gene status has been investigated for an association with clinical outcome. Over multiple retrospective series and prospective trials, VHL status (and other VHL pathway elements, such as hypoxia-inducible factor expression) has not been consistently associated with response to vascular endothelial growth factor (VEGF)-targeted agents.^{220–222} CA-IX, a member of the carbonic anhydrase family, regulates pH during hypoxia and is a product of the hypoxia inducible transcription factor (HIF) complex overexpression. The vast majority of ccRCC tumor samples stain positive for CA-IX and high CA-IX staining (>85% staining by immunohistochemical analysis) was found to be an independent favorable prognostic indicator of survival in patients with metastatic ccRCC.²²³ Retrospective data initially suggested CA-IX to be potentially associated with response to high-dose interleukin (IL)-2.²²⁴ However, the prospective SELECT trial failed to confirm this finding and thus there remain no predictive biomarkers to identify the small percentage of patients who will have a complete response to high-dose IL-2.²²⁵ Single nucleotide polymorphisms, which are natural variations in tumor and/or germline DNA sequences, have also been investigated in relation to targeted therapy efficacy and toxicity in RCC.^{226–228} While several retrospective series have found associations between single nucleotide polymorphisms associated with the VEGF pathway and/or drug metabolism with outcome, none have been consistent or robust enough to currently affect clinical practice. Finally, clinical markers, such as treatment-induced hypertension, have been explored. Several retrospective data sets have identified a strong association of treatment-induced hypertension and clinical outcome in response to VEGF-targeting agents.^{229,230} This has been identified across mechanism of agent and including non-RCC diseases.²³¹ The precise biologic mechanism underlying this observation remains to be elucidated. In addition, this observation requires treatment of all patients initially and as a result does not spare ineffective therapy for patients who will not benefit.

Systemic Therapy

Although several active agents now exist for metastatic RCC (as discussed subsequently), they are considered noncurative for the majority of patients and thus require chronic therapy. Thus, benefits must be weighed against the toxicity, time commitment, and cost. There exists a subset of patients with metastatic RCC with low-volume slow-growing disease in which withholding systemic therapy until radiographic progression has occurred may be a reasonable approach. Further investigation into this strategy is ongoing.

Historically, progestational agents such as medroxyprogesterone acetate were investigated in metastatic RCC.^{232,253} These reports documented some tumor regression and symptom reduction, largely applied to a very advanced, symptomatic population of RCC patients. Multicenter randomized trials demonstrate uniformly low response rates.²³⁴ In the current era, progestational agents may be useful for symptom palliation, but do not appear to have any significant antitumor effects.

Due to success in other solid tumors, chemotherapy for advanced RCC has been extensively studied during the last four decades. A summary of clinical trials from 1983 to 1993 noted a 6% overall response rate in 4,093 patients with advanced RCC.²³⁵ Another report of 51 published phase 2 clinical trials ($n = 1,347$) involving 33 chemotherapeutic agents noted an overall response rate of 5.5%.²³⁶ Combinations of 5-fluorouracil and analogues with gemcitabine have produced modestly higher response rates, on the order of 10% to 15%.^{237,238} Similarly, the addition of chemotherapy to cytokine regimens has not resulted in significant benefit over cytokines alone when investigated in phase 3 trials.^{239,240} A report of 18 metastatic RCC patients with sarcomatoid histologic features and/or rapidly progressing disease treated with doxorubicin and gemcitabine noted a 28% objective response rate (ORR), potentially identifying a subset of patients with RCC where chemotherapy may have some utility.²⁴¹ Overall, chemotherapy currently has little to no role in the treatment of metastatic RCC pending further study of novel chemotherapeutic agents or combinations, or perhaps through additional patient selection efforts.

Immunotherapy

IL-2 and IFN had been the standard of care for patients with metastatic RCC until the development of targeted therapy. These agents are nonspecific cytokines that presumably have an antitumor effect through stimulation of an antitumor immune response that is not adequate in the patient prior to therapy. Specific insights into mechanism(s) of action are still lacking after decades of use and further clinical and/or molecular markers to predict benefit are lacking.

Bolus high-dose intravenous IL-2 treatment, as initially described many years ago, leads to sustained responses in a small subset of patients.²⁴² However, later randomized trials failed to demonstrate a benefit over lower-dose cytokine regimens for the entire cohort, likely reflecting the small number of patients benefiting.^{243,244} The durable complete remissions that occur in 5% to 7% of patients, however, served as the basis for US Food and Drug Administration (FDA) approval of high-dose IL-2 in the United States in 1992.^{245–247} Thus, given the noncurative nature of targeted therapy and considering only a small fraction of patients are eligible for this toxic treatment, IL-2 remains a viable treatment option for patients with ccRCC and a good performance status.

IFN (given only in low doses in RCC) has also been employed. While never approved by the FDA specifically for this indication, two large randomized trials demonstrated that IFN improved OS compared with medroxyprogesterone²³⁴ or vinblastine.²⁴⁸ IFN thus was a community standard for metastatic RCC prior to targeted therapy and served as the comparator arm in many trials. Single-agent IFN is generally no longer used. As noted in the following, IFN combined with bevacizumab is a currently approved regimen

for metastatic RCC, although in practice many oncologists use bevacizumab monotherapy as the IFN likely adds some benefit, but significantly more toxicity. Multiple attempts over many decades to improve on the modest effects of IL-2 and IFN, including combinations of cytokines, combinations with chemotherapy, and cytokine sequencing, have failed.^{249–252}

Investigational Immunotherapy

RCC has long been considered responsive to immune manipulation due to the modest response to cytokines noted previously. Additional efforts are ongoing to expand the application of immunotherapy. Specifically, IMA901, a vaccine composed of multiple tumor-associated peptides, has been found to be safe and to induce antitumor immunity in patients with metastatic RCC.²⁵³ Based in part on data that sunitinib may favorably modulate the immune repertoire,²⁵⁴ a phase 3 trial that randomized patients with metastatic RCC to sunitinib alone or sunitinib in combination with IMA901 has completed accrual. In addition, an autologous dendritic cell vaccine derived from primary patient tumor-specific antigens demonstrated favorable results in phase 2 studies and is currently in phase 3 testing.²⁵⁵

In addition, checkpoint inhibitors, agents that stimulate antitumor immunity by releasing the natural “brake” of the immune system, have entered clinical testing in metastatic RCC with promising initial results.^{256,257} Nivolumab, which binds to programmed death receptor 1 is one such checkpoint inhibitor. A phase I expansion RCC cohort reported a 30% ORR associated with durable responses even after therapy was stopped. Additional phase II trials and a phase III registration trial are ongoing. In addition, several anti-programmed death receptor 1 agents and antibodies against its ligand, PD-L1, are being investigated in metastatic RCC.

Vascular Endothelial Growth Factor–Targeted Therapy

RCC presents a unique clinical setting for the application of antiangiogenic approaches. Through mutations in the *VHL* gene and/or other genetic events that result in the deregulated expression of the hypoxia inducible transcription factors, HIF-1 α and/or HIF-2 α , a large cohort of hypoxia-responsive genes is induced, including VEGF as one of the classic transcriptional targets.²⁵⁸ There is a direct link between *VHL* mutation and upregulation of angiogenesis-promoting proteins, including VEGF and platelet-derived growth factor (PDGF). Thus, increased expression of these proteins and the consequences of that increased expression are central events in the development of most RCC tumors. VEGF is the major factor responsible for tumor angiogenesis. Several treatment strategies have thus been investigated in metastatic RCC to block components of the angiogenic signaling pathway components, such as VEGF.

Sunitinib

Sunitinib (Sutent, Pfizer Inc., New York, NY) is an oral drug with in vitro and cellular inhibitory activity against several related protein tyrosine kinase receptors, including PDGF-receptor-beta, stem cell factor receptor (KIT), and Fms-like tyrosine kinase-3 (FLT-3), as well as VEGF receptors 1, 2, and 3.^{259,260} Sunitinib was initially studied in metastatic RCC in two sequential phase 2 trials in cytokine-refractory patients that demonstrated an ORR of approximately 40% with a combined median PFS of 8.2 months (Table 63.8).^{261,262} The most common adverse events with sunitinib are fatigue, diarrhea, mucositis, hand-foot syndrome, and hypertension. A phase 3 randomized trial of first-line sunitinib versus IFN- α in 750 patients with metastatic ccRCC showed statistically significant improvements in ORR and PFS with sunitinib compared with IFN. Median PFS as assessed by an

TABLE 63.8

Summary of Target Agents in Metastatic Renal Cell Carcinoma

Treatment	Response Rate	Progression-Free Survival	Overall Survival
<i>VEGF Receptor Inhibitors</i>			
Sunitinib	30% to 47%	9.5 to 11 mo in treatment-naïve patients 8.4 mo in cytokine refractory patients	29.3 mo in untreated patients
Pazopanib	30%	8.4 to 9.2 mo (11.1 mo in treatment-naïve patients)	28.4 mo in untreated patients
Sorafenib	2% to 10%	5.7 to 9 mo in treatment-naïve patients 5.5 mo in treatment-refractory patients	17.8 to 19.2 mo in treatment-refractory patients
Axitinib	19%	6.7 mo (second-line)	20.1 mo in treatment-refractory patients
<i>VEGF Ligand-Binding Agents</i>			
Bevacizumab	10% to 13% as monotherapy 26% to 31% in combination with IFNA	8.5 mo in treatment-naïve patients as monotherapy 8.5 to 10.2 mo in treatment-naïve patients in combination with IFNA 4.8 mo in cytokine-refractory patients	18.3 to 23.3 mo
<i>mTOR-Inhibiting Agents</i>			
Temsirolimus	7% to 9%	3.7 mo (vs. 1.9 mo for IFNA monotherapy; $p = 0.0001$) in treatment-naïve patients 5.8 mo in treatment-refractory patients	10.9 mo (vs. 7.3 mo for IFNA; $p = 0.008$)
Everolimus	1%	4.9 mo (vs. 1.9 mo for placebo-treated patients) in refractory patients	14.8 mo (vs. 14.4 mo for placebo-treated patients; $p = 0.177$)

VEGF, vascular endothelial growth factor; IFNA, interferon-alfa; mTOR, mammalian target of rapamycin.

independent review was 11 months in the sunitinib arm versus 5 months in the IFN arm, and ORR was 31% versus 6%, respectively ($p < 0.000001$; see Table 63.8).²⁶³ Median OS was 26.4 months for sunitinib versus 21.8 months for IFN ($p = 0.051$).²⁶⁴ The OS data are a reflection of not only sunitinib activity, but several other active drugs that patients received upon progression, resulting in notably prolonged median survival times compared to historical controls. Sunitinib was approved by the FDA as monotherapy for advanced RCC in January 2006 and remains an initial standard of care in metastatic RCC.

Pazopanib

Pazopanib is an oral multitargeted tyrosine kinase inhibitor that targets VEGF receptors 1 to 3, PDGF receptor, and c-kit. A phase 2 study initially designed as a randomized discontinuation study was revised to an open-label study based on the response rate of a planned interim analysis. This study evaluated 255 patients with metastatic RCC who received pazopanib 800 mg once daily; 69% had no prior treatment and 31% had received one prior treatment. The overall response rate was 35%, the median PFS was 52 weeks, and the median duration of response was 68 weeks. The main adverse effects were diarrhea and fatigue, and the most common grade 3-4 side effect was hypertension. Alanine transaminase and aspartate transaminase elevation occurred in 54% of patients. In October 2009, the FDA approved pazopanib for the treatment of metastatic RCC, based on the results of a phase 3 trial. This study evaluated 435 patients with advanced ccRCC with either no previous treatment or with one prior cytokine treatment. Patients were randomized (2:1) to receive pazopanib 800 mg daily or placebo. The response rate for patients treated with pazopanib was 30% and the median duration of response was 58.7 weeks. Median PFS was 9.2 months in the pazopanib group and 4.2 months in the placebo group (HR = 0.46; $p < 0.0001$; see Table 63.8). PFS was prolonged in both treatment naïve patients (11.1 months versus 2.8 months;

$p < 0.0001$) and in cytokine-pretreated patients (7.4 months versus 4.2 months; $p < 0.001$).

Pazopanib has been further studied in a noninferiority study compared to sunitinib in the front-line treatment of metastatic RCC (COMPARZ study).²⁶⁵ Over 1,100 patients with previously untreated ccRCC were randomized to either pazopanib or sunitinib (1:1) in a noninferiority design. Median PFS was 9.5 months with sunitinib and 8.4 months with pazopanib, with a hazard ratio of 1.047 (95% CI = 0.898 to 1.220). The upper bound of the confidence interval was < 1.25 , satisfying the predefined boundary for noninferiority. OS was approximately 29 months in both arms. Certain toxicities were more common with sunitinib including fatigue and hand-foot syndrome, while pazopanib produced greater hepatic abnormalities. This trial demonstrated that both sunitinib and pazopanib are appropriate front-line treatment options in metastatic RCC and that a differing toxicity profile may allow the physician to tailor therapy to each individual patient.

Sorafenib

Sorafenib (Nexavar, Bayer Pharmaceuticals and Onyx, Leverkusen, Germany) is an oral multikinase inhibitor that inhibits VEGF receptors 1 to 3, PDGF-receptor-beta, and the serine threonine kinase Raf-1, which acts through the RAF/MEK/ERK signaling pathway and plays a role in cellular proliferation and tumorigenesis.^{266,267} In an initial sorafenib trial, metastatic RCC patients ($n = 202$) were treated with 12 weeks of continuous oral sorafenib 400 mg bid and patients with tumor burden increase or decrease within 25% of baseline were randomized to placebo or to continuation of sorafenib. A PFS advantage of 24 versus 6 weeks ($p = 0.0087$) was demonstrated in the randomized cohort of 65 patients at 12 weeks postrandomization.²⁶⁸ A subsequent 905 patient, placebo-controlled, randomized trial of sorafenib 400 mg bid in treatment-refractory, metastatic RCC reported a PFS advantage in the sorafenib arm of 5.5 months versus 2.8 months for

placebo ($p < 0.000001$; see Table 63.8). A 2% RECIST-defined ORR was seen in the sorafenib arm, but 74% of patients overall had some degree of tumor burden shrinkage thus accounting for the PFS benefit. The median OS was 19.3 months for patients in the sorafenib group and 15.9 months for patients in the placebo group (HR = 0.77; 95% CI = 0.63 to 0.95; $p = 0.02$), which did not reach prespecified statistical boundaries for significance.²⁶⁹ Common toxicity in the sorafenib trials has included dermatologic (hand-foot syndrome), fatigue, diarrhea, and hypertension. Sorafenib was approved by the FDA as monotherapy for advanced RCC in December 2005. A randomized phase 2 trial of sorafenib versus IFN in untreated metastatic RCC failed to demonstrate a difference in median PFS between the two treatment arms.²⁷⁰ Sorafenib has thus assumed a small, salvage role in the treatment of metastatic RCC.

Bevacizumab

Bevacizumab (Avastin, Genentech, South San Francisco, CA) is a monoclonal antibody that binds and neutralizes circulating VEGF protein.²⁷¹ The activity of this agent in RCC was initially identified by small randomized trials.^{272,273} Two phase 3 trials were subsequently reported and led to FDA approval of bevacizumab plus IFN for advanced RCC. One phase 3 trial randomized 649 untreated patients with metastatic RCC to treatment with IFN (Roferon, Roche, Basel, Switzerland) plus placebo infusion or to IFN plus bevacizumab infusion 10 mg/kg every 2 weeks.²⁷⁴ A significant advantage for bevacizumab plus IFN was observed for ORR (31% versus 13%, $p < 0.0001$) and PFS (10.2 months versus 5.4 months, $p < 0.0001$; see Table 63.8). A second multicenter phase 3 trial, conducted in the United States and Canada through the Cancer and Leukemia Group B, was nearly identical in design with the exception of lacking a placebo infusion and not requiring prior nephrectomy.²⁷⁵ In this trial, the median PFS was 8.5 months in patients receiving bevacizumab plus IFN (95% CI = 7.5 to 9.7) versus 5.2 months (95% CI = 3.1 to 5.6) for IFN monotherapy ($p < 0.0001$; see Table 63.8). Also, among patients with measurable disease, the ORR was higher in patients treated with bevacizumab plus IFN (25.5%) than for IFN monotherapy (13.1%; $p < 0.0001$). OS data are similar to the other agents with a numerical advantage in median survival not meeting statistical significance, reflecting the large proportion of patients who receive subsequent active therapy. The contribution of IFN to the antitumor effect of this regimen is unclear at present, although preliminary results indicate a longer PFS and higher response rate than expected with bevacizumab monotherapy.²⁷² Combination IFN and bevacizumab therapy is more toxic than either as monotherapy, notable for fatigue, anorexia, hypertension, and proteinuria. Thus, the use of IFN with bevacizumab requires evaluation of the risk/benefit ratio for each patient.

Axitinib

Axitinib is a potent VEGF receptor family inhibitor studied in several settings in metastatic RCC. Initial studies in cytokine- and sorafenib-refractory patients demonstrated objective responses and disease control, which prompted further development.^{276,277} The phase 3 AXIS trial randomized 723 patients with metastatic RCC (refractory to either sunitinib, cytokines, bevacizumab, or temsirolimus) to axitinib or sorafenib.²⁷⁸ The median PFS was 6.7 months for axitinib versus 4.7 months for sorafenib (HR for disease progression or death of 0.665 [95% CI = 0.544 to 0.812]; $p < 0.0001$). ORR was 19.4% versus 9.4% with axitinib and sorafenib, respectively. This trial resulted in FDA approval of axitinib for previously treated metastatic RCC. A separate trial examined axitinib versus sorafenib in the front-line setting.²⁷⁹ Despite a numerical advantage for PFS for axitinib, this trial did not meet its stringent predefined efficacy endpoint, and thus axitinib is largely used in the second-line setting in RCC.

Mammalian Target of Rapamycin–Targeted Therapy

Temsirolimus

Temsirolimus is an inhibitor of mTOR, a molecule implicated in multiple tumor-promoting intracellular signaling pathways, including regulation of transcription factors involved in VEGF expression, such as HIF.²⁸⁰ A phase 2 trial in patients with treatment-refractory, metastatic RCC randomized 111 patients to temsirolimus at one of multiple dose levels (25 mg, 75 mg, or 250 mg intravenously weekly).²⁸¹ The ORR was 7% with additional patients demonstrating minor responses (see Table 63.8). Retrospective assignment of risk criteria to patients in this study identified a poor-prognosis group with a median OS of 8.2 months compared to 4.9 months for historical IFN-treated patients.²¹⁵ Loss of phosphatase and tensin homolog and/or activation of Akt (upstream regulators of the mTOR expression) may be more common in poor-risk patients and thereby potentially increase the relevance of mTOR-targeted therapy in this subgroup.

A subsequent randomized phase 3 trial was conducted in patients with metastatic RCC ($n = 626$) and three or more adverse risk features as defined by existing prognostic schema (see Table 63.7).^{211,215} Patients were randomized equally to receive IFN (18 million units subcutaneously) three times a week, temsirolimus 25 mg intravenously weekly, or temsirolimus 15 mg intravenously weekly and IFN (6 million units subcutaneously) three times a week. The primary study endpoint was OS and the study was powered to compare each of the temsirolimus arms to the IFN arm. Both temsirolimus-containing arms demonstrated a PFS advantage versus IFN (3.7 months for each arm versus 1.9 months; $p = 0.0001$ for temsirolimus monotherapy and $p = 0.0019$ for temsirolimus plus IFN). Patients treated with temsirolimus monotherapy had a statistically longer survival than those treated with IFN alone (10.9 months versus 7.3 months, $p = 0.0069$). OS of patients treated with IFN and temsirolimus + IFN were not statistically different (7.3 months versus 8.4 months, $p = 0.6912$). Even though temsirolimus has demonstrated activity in poor-risk RCC, it is not clear that this agent has more activity than the VEGF-targeted agents in this subset, as VEGF-targeted agents have shown activity, albeit in limited subsets, in poor-risk patients.

Everolimus

Everolimus is an oral rapamycin analogue that inhibits mTOR. A phase 3 study evaluated 410 patients previously treated with sorafenib, sunitinib, or both who were randomized (2:1) to receive everolimus 10 mg once daily or placebo.²⁸² PFS was significantly longer in the everolimus group (HR = 0.30, 95% CI = 0.22 to 0.40; $p < 0.0001$). Median PFS in the everolimus group was 4.9 months versus 1.9 months in the placebo group. Partial response in the everolimus group occurred in 1% of the patients, and 63% (versus 32% in the placebo group) had disease stabilization for at least 56 days. Most common adverse effects of everolimus were stomatitis, rash, fatigue, asthenia, and diarrhea. Stomatitis, fatigue, infection, and pneumonitis were the most common grade 3/4 toxicities. On the basis of these results, everolimus was approved for the treatment of metastatic RCC refractory to sunitinib and/or sorafenib.

A recent trial (RECORD-3) randomized 471 patients with previously untreated metastatic RCC to either sunitinib or everolimus, with crossover at progression.²⁸³ This trial, reported to date only in abstract form, demonstrated an advantage to sunitinib in response rate (27% versus 8%), PFS (10.7 months versus 7.9 months), and OS (32 months versus 22 months). In addition, all subsets examined (non-clear cell, clear cell, and prognostic groups) favored sunitinib. These data support the use of everolimus only in a refractory setting and confirm a hypothesis that VEGF targeting is a superior initial strategy for RCC therapy.

Second-Line Therapy

As noted previously, axitinib has been studied and FDA-approved as second-line therapy in metastatic RCC with a PFS advantage over sorafenib. Still debated is the role of everolimus versus a VEGF agent in this setting. The INTORSECT trial randomized patients with metastatic RCC refractory to prior sunitinib to receive either temsirolimus or sorafenib.²⁸⁴ Although there was no significant difference in PFS (approximately 4 months in both arms), an OS advantage to sorafenib was observed. These data lend support to the hypothesis that continued VEGF targeting is of benefit in metastatic RCC, although no PFS advantage was demonstrated and the mTOR inhibitor used in this trial had not been specifically shown to have benefits in this setting.

Current Status of Systemic Therapy in Metastatic Renal Cell Carcinoma

Of note, several trials have been conducted attempting to combine the targeted therapies discussed previously. None have demonstrated an advantage over monotherapy, in large part due to excessive toxicity in the combination arms.^{285,286} Sunitinib and pazopanib are the most commonly used front-line agents based in large part on the COMPARZ efficacy data as well as their tolerability and oral formulation. There is no proven sequence of agents or ability to predict response to any given agent, and thus the current

standard of care is an empiric sequence of targeted therapy monotherapy, notwithstanding the select patient who initially receives high-dose IL-2.

CONCLUSION AND FUTURE DIRECTIONS

The last 20 years have seen a tremendous increase in our understanding of the tumor biology of the heterogeneous tumors within the family of renal cancers. Insights beginning with the clinical observation of the hypervascularity of these tumors, continuing with rigorous scientific investigation of familial cases of RCC, and culminating in the development of treatments based on the VEGF pathway, have made the last decade a rich period of expansion in treatment options for RCC. With increasing availability of next generation sequencing, the potential for subsequent discoveries to advance our understanding of and therapies for this often lethal malignancy remains considerable. Through multidisciplinary explorations of these fascinating neoplasms, renal cancer can continue to pace oncologic discoveries for the next 20 years as well.

64 Molecular Biology of Bladder Cancer

Margaret A. Knowles and Carolyn D. Hurst

INTRODUCTION

There has been rapid progress in elucidating the molecular changes that underlie bladder cancer development. A wealth of data is now available that identifies several critical drivers of the malignant urothelial phenotype, some of which have clear potential for therapeutic targeting. Most studies have focused on urothelial carcinomas (UC), which comprise the majority (>90%) of tumors diagnosed in the Western world. This chapter will provide an overview of somatic molecular features of UC identified by genomic, epigenomic, and expression profiling. There is also much information about germline variants that confer increased risk of UC development and the reader is referred to recent reviews on this topic.^{1,2}

At diagnosis, approximately 60% of UCs are noninvasive (stage Ta) papillary lesions. These commonly recur, but progression to muscle invasion is infrequent (10% to 15%) and prognosis is good. In contrast, tumors that are muscle invasive at diagnosis (\geq T2) have poor prognosis (<50% survival at 5 years). Stage T1 tumors, which have penetrated the epithelial basement membrane but not invaded muscle, represent a clinically challenging and molecularly heterogeneous group with features related to each of the two major groups. The distinction of the two major groups is supported by a wealth of molecular information, and a “two-pathway” model for UC pathogenesis has long dominated thinking about this cancer type and its clinical management. Many genomic alterations and expression of specific genes relate directly to these groups and will be discussed in this context here. Global expression and epigenetic alterations show less direct relationships and will be discussed together. Importantly, recent molecular information provides strong evidence for multiple molecular subgroups that are independent of tumor grade and stage. This new molecular classification, which shows great promise of clinical relevance, is described in a separate section.

KEY MOLECULAR ALTERATIONS IN STAGE Ta UROTHELIAL CARCINOMA

Low-grade stage Ta papillary UC (“superficial” UC) are genomically stable, often with near-diploid karyotype. Common features are activation of *FGFR1*, *FGFR3*, *PIK3CA*, and *CCND1* genes by mutation or upregulated expression and mutational inactivation of *CDKN2A*, *STAG2*, and *TSC1*. The most common event recorded to date is mutation of the promoter region of telomerase reverse transcriptase (*TERT*).

FGF Receptors

Activating point mutations in FGF receptor 3 (*FGFR3*) are present in \geq 70% of cases.³ These are in hot-spot codons in exons 7, 10, and 15 (Fig. 64.1A) and are all predicted to constitutively activate the receptor.⁴ Mutations are also found in urothelial papilloma, a likely precursor of superficial UC.⁵ Increased expression of mutant *FGFR3* is common in these tumors.⁶ MicroRNAs (miRNAs) miR-99a/100, which are commonly downregulated in non-muscle-invasive (NMI)

tumors, are negative regulators of *FGFR3* expression.⁷ Transcriptional regulation by the p53 family member p63 has also been demonstrated.⁸ In cultured normal human urothelial cells (NHUC), expression of mutant *FGFR3* leads to activation of the RAS-MAPK pathway and PLC γ , leading to overgrowth of cells at confluence,⁹ and suggesting a possible contribution of *FGFR3* activation to urothelial hyperplasia in vivo. An alternative mechanism of *FGFR3* activation in a subset of cases (2% to 5%) is chromosomal translocation to generate a fusion protein. All *FGFR3* fusions identified to date show loss of the final exon of *FGFR3* and fusion in-frame to *TACC3* (transforming acid coiled-coil containing protein 3), or in one case to *BAIAP2L1* (BAIL-associated protein 2-like 1) also known as *IRTKS* (insulin receptor tyrosine-kinase substrate).¹⁰ It is not yet clear whether this activation mechanism is related to tumor grade or stage. These fusion proteins are highly activated and transforming oncogenes. FGF1 and FGF2 are expressed in UC tissues and cell lines,^{11,12} FGF2 is detected in the urine of patients with bladder cancer,¹³ and expression has been detected in the urothelial stroma.¹⁴ Thus, it is also likely that both autocrine and paracrine FGF production contributes to *FGFR3* activation in UC, particularly in those tumors with expression of wild-type protein (Fig. 64.1B).

Activation of the RAS-MAPK pathway in Ta tumors may also be achieved by mutation of one of the RAS genes (most commonly *HRAS* or *KRAS2*), and this is mutually exclusive with *FGFR3* mutation.¹⁵ More than 80% of noninvasive bladder tumors are predicted to have RAS-MAPK pathway activation via these mechanisms (Fig. 64.2A). Compatible with this, urothelial expression of an activated Ras transgene in mice leads to hyperplasia and papillary tumors,¹⁶ suggesting an important role for activation of the RAS-MAPK pathway in the generation of urothelial hyperplasia.

In NMI UC, *FGFR3* mutation is associated with favorable outcome.¹⁷⁻¹⁹ High *FGFR3* expression, normal staining pattern for CK20, and low proliferative index in papillary urothelial neoplasms of low malignant potential²⁰ is reported to identify tumors that do not recur.²¹

FGFR3 is considered a good therapeutic target in superficial UC, though early clinical application is most likely in muscle invasive rather than superficial UC (see the following). Several studies indicate that inhibition of mutant *FGFR3* by knockdown or inhibition using small molecules or antibodies has a profound effect on UC cell phenotype, including inhibition of xenograft growth in vivo.²²

Upregulated expression of the related receptor *FGFR1* is also found in Ta tumors.²³ No mutations have been detected, and there is infrequent gene amplification.²⁴ Ectopic expression of *FGFR1* in NHUC in the presence of FGF2 ligand, activates the RAS-MAPK pathway and PLC γ , and promotes cell survival.²³ Currently, there is no information on the prognostic significance of these alterations.

PIK3CA

The phosphatidylinositol-3 kinase (PI3K) pathway plays a pivotal role in signaling from receptor tyrosine kinases (Fig. 64.2A). Activating mutations of the p110 α catalytic subunit (*PIK3CA*) are found in UC, most commonly in low-grade, stage Ta tumors (~25%).²⁵⁻²⁸

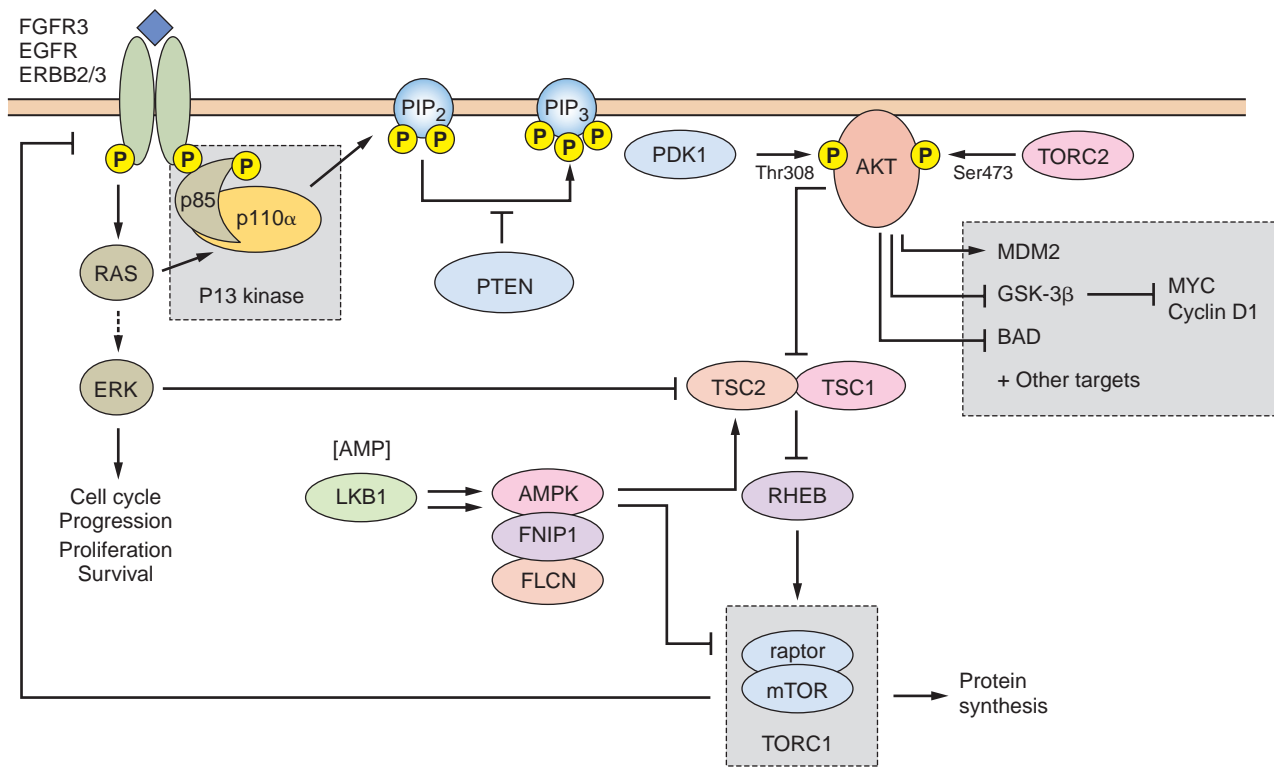

Figure 64.1 (A) *FGFR3* mutations identified in bladder cancer. Positions of hot-spot mutations in exons 7, 10, and 15 that are found in bladder cancer are shown in relation to protein structure. The relative frequency of the more common mutations is given as a percentage. Igl, IgII, IgIII, immunoglobulinlike domains; TM, transmembrane domain; TK, tyrosine-kinase domain. **(B)** Mechanisms of *FGFR3* activation in bladder cancer. *FGFR3* can be activated by ligand-dependent and -independent mechanisms. Ligand-dependent activation may be via increased expression of wild-type *FGFR3*, increased production of FGFs by tumor or stromal cells, with or without upregulated *FGFR3* expression, or through expression of splice variants with the ability to bind a wider range of FGF ligands. Ligand independent activation can be achieved by point mutation that facilitates receptor dimerization or by the generation of fusion proteins that constitutively dimerise.

The mutation spectrum (Fig. 64.2B) differs significantly from that found in other cancers. Mutations E542K and E545K in the helical domain are most common (22% and 60%, respectively) and the kinase domain mutation H1047R, which is the most common mutation in other cancers, is less frequent. The selective pressure for helical domain mutation in UC is not fully understood. E542K and E545K forms require interaction with RAS-GTP but not binding to p85, the regulatory subunit of PI3K, whereas H1047R depends on p85 binding and is active in the absence of RAS binding.²⁹ This suggests potential cooperation between helical domain PIK3CA mutant proteins and events in UC that activate RAS. Compatible with this, *PIK3CA* and *FGFR3* mutations are commonly found together.^{25–28} Mutant *PIK3CA* confers a proliferative advantage at confluence and stimulates intraepithelial movement in NHUC,

with higher activity of helical domain than kinase domain mutants in this cell context.³⁰ Several other mechanisms of PI3K pathway activation have been identified in UC, though none of these are common in noninvasive tumors (Table 64.1).

STAG2

Inactivating mutations in the cohesin complex component *STAG2* (Xq25) have been identified in UC.^{31–34} Mutations are most common in stage Ta tumors (20% to 36%) and are predominantly inactivating, suggesting a tumor suppressor function. The cohesin complex, which in human cells contains SMC1A, SMC3, RAD21, and either *STAG2* or *STAG1*, mediates

A

B

Figure 64.2 (A) Oncogenic signaling via the RAS-MAPK and PI3K pathways. Growth factor-mediated signaling or mutational activation of RAS oncogenes can activate both of these pathways. Signaling via the RAS/RAF/MEK/ERK cascade leads to phosphorylation of many substrates that can have multiple cellular effects depending on the intensity and duration of signaling. In many situations, proliferation is induced. Activated receptor tyrosine kinases bind p85, the regulatory subunit of PI3K, and recruit the enzyme where it phosphorylates phosphatidylinositol-4, 5-bisphosphate (PIP₂) to generate PIP₃, which in turn recruits PDK1 and AKT to the membrane, where AKT is activated by phosphorylation to regulate a wide range of target proteins (not all shown). Among these are cyclin D1 and MDM2, which are upregulated either directly or indirectly, resulting in a positive stimulus via the RB or p53 pathways, respectively. AKT also phosphorylates and inactivates tuberin the TSC2 gene product, leading to activation of mTOR complex 1 (TORC1), which controls protein synthesis. The TSC1 product hamartin forms an active complex with tuberin, and loss of function of either protein leads to dysregulated mTOR signaling. MYC expression is induced as a consequence of both by ERK and AKT signaling. Many genes in these pathways show mutation [*FGFR3*, *PIK3R1* (p85 α), *PIK3CA* (p110 α), *HRAS*, *KRAS2*, *PTEN*, *AKT1*, *TSC1*, *TSC2*] or upregulated expression (EGFR, ERBB2, ERBB3, FGFR1) in bladder cancer. (B) *PIK3CA* mutations identified in bladder cancer in relation to protein structure. Pie charts show proportions of common helical domain (E542, E545) and kinase domain (H1047) mutations in bladder and other cancers. Data from COSMIC (<http://cancer.sanger.ac.uk/cancergenome/projects/cosmic/>; accessed November 15, 2013).

TABLE 64.1

Genetic Changes Identified in Stage Ta Bladder Tumors

Gene (Cytogenetic Location)	Alteration	Frequency (%)
Oncogenes		
<i>HRAS</i> (11p15)/ <i>NRAS</i> (1p13)/ <i>KRAS2</i> (12p12)	Activating mutations	15 ^{15,27,28,221}
<i>FGFR3</i> (4p16)	Activating mutations	60–80 ^{3,222}
<i>CCND1</i> (11q13)	Amplification/overexpression	10–20 ^{58,223–225}
<i>PIK3CA</i> (3q26)	Activating mutations	27 PUNLMP; 16–30 Ta ^{25,26}
<i>MDM2</i> (12q13)	Overexpression/amplification	~30 overexpression; amplification infrequent ^{58,85,226}
Tumor Suppressor Genes		
<i>CDKN2A</i> (9p21)	Homozygous deletion/mutation/methylation	HD 20–30 ^{40,41,227,228} LOH ~60 ²²⁹
<i>PTCH</i> (9q22)	Deletion/mutation	LOH ~ 60; mutation frequency low ^{43,44}
<i>TSC1</i> (9q34)	Deletion/mutation	LOH ~ 60; mutation ~12 ^{26,27,48,230}
<i>STAG2</i> (Xq25)	Deletion/mutation	34–36 ^{33,34}
<i>KDM6A</i> (Xp11)	Mutation	10–30 ^{31,32,140}
<i>ARID1A</i>	Mutation	10 ^{31,32}
DNA Copy Number Changes^a

PUNLMP, papillary urothelial neoplasms of low malignant potential; HD, homozygous deletion; LOH, loss of heterozygosity.

cohesion between sister chromatids following DNA replication to ensure correct chromosomal segregation. Mutations in *STAG2* in glioblastoma have been reported to cause aneuploidy³⁵ but this relationship is not apparent in UC, where most mutations have been found in low grade/stage, genomically stable tumors, and there is no association of mutation with chromosomal copy number changes.^{31,34}

In addition to its well-documented functions during cell division, cohesin regulates gene expression through mechanisms involving DNA looping and interactions with transcriptional regulators such as CTCF, though evidence to date suggests that these roles are mainly related to *STAG1*-cohesin.³⁶ Functional studies are now required to elucidate the consequences of *STAG2* loss of function in UC.

Telomerase Reverse Transcriptase Gene Promoter

The most common genomic alterations identified in UC of all grades and stages are mutations in the promoter of the telomerase reverse transcriptase gene (*TERT*) in more than 80% of cases.^{37,38} Mutations are predominantly in two hotspot positions [-124 bp (G>A) and -146 bp (G>A) relative to the ATG translational start site], and this has facilitated the design of robust methods of

detection. Examination of *TERT* expression in UC tissues has not revealed an effect of mutation on expression,³⁷ so that the functional significance of these mutations remains to be determined. Nevertheless, the ease with which these mutations can be detected in urine sediments^{37,38} is likely to make a major contribution to the development of urine-based assays for detection of bladder tumors of all grades and stages.

Other Genomic Alterations in Noninvasive Urothelial Carcinoma

These tumors are often near diploid. The most common genomic alteration is loss of heterozygosity (LOH) or copy number loss of chromosome 9, often an entire homolog. More than 50% of UC of all of grades and stages show chromosome 9 LOH. A critical region on 9p21 and at least three regions on 9q (9q22, 9q32–q33, and 9q34) have been identified. Candidate genes within these regions are *CDKN2A* (p16/p14ARF) and *CDKN2B* (p15) at 9p21,^{39–42} *PTCH* (Gorlin syndrome gene) at 9q22,^{43,44} *DBC1* at 9q32–q33,^{45–47} and *TSC1* (tuberous sclerosis syndrome gene 1) at 9q34^{26,48,49} (Table 64.1).

CDKN2A (9p21) encodes the two cell-cycle regulators, p16 and p14ARF. p16 is a negative regulator of the RB pathway and p14ARF, a negative regulator of the p53 pathway (Fig. 64.3).

Figure 64.3 Key interactions in the RB and p53 pathways. The *CDKN2A* locus encodes p16 and p14ARF that act as negative regulators of the RB and p53 pathways, respectively. This interrelated signaling network is central to tumor suppression via the mechanisms of cell-cycle arrest and apoptosis. Stimulation by mitogens induces cyclin D1 expression. Phosphorylation of RB1 by CDK4-cyclin D1 complexes releases E2F family members to induce expression of genes required for progression into S phase. The cyclin D-CDK4 complexes also sequester p27 and p21 (not shown). This allows formation of cyclin E-CDK2, which reinforces the inactivation of RB1. p16 negatively regulates this process by interacting with CDK4. The p53 pathway responds to stress signals (e.g., DNA damage). p21 expression is induced and this leads to cell-cycle arrest. MDM2 is a ubiquitin ligase responsible for inactivation of p53. In turn, p53 regulates MDM2 expression providing a negative feedback loop. The p53 and RB pathways are connected by p14ARF, which sequesters (inactivates) MDM2 in the nucleus and is upregulated by E2Fs and in response to mitogenic signaling. Overexpression of E2Fs and oncogenes such as *MYC* can both result in p53-triggered cell-cycle arrest via p14ARF. RTK; receptor tyrosine kinase.

Inactivation of this locus in UC is commonly by homozygous deletion (HD). LOH of 9p, HD of *CDKN2A*, and loss of expression of p16 in NMI UC is predictive of reduced recurrence-free interval.^{50–52} Mouse knockout and in vitro experiments indicate that p16 and/or p14ARF may be haploinsufficient.^{53,54} In human UC, this may affect the biology of approximately 45% of cases that have LOH or reduced copy number of 9p21.

On 9q, three genes are implicated. *PTCH*, the Gorlin syndrome gene (9q22), shows infrequent mutation,⁴⁴ but many tumors have reduced mRNA expression.⁴³ *DBC1* (9q33) shows HD in a few tumors⁵⁵ and no mutations, but is commonly silenced by hypermethylation.^{45,56} *TSC1* is the best-validated 9q tumor suppressor gene. *TSC1* in complex with *TSC2* negatively regulates the mTOR branch of the PI3K pathway (Fig. 64.2A).

Biallelic inactivation of *TSC1* is found in 12% to 16% of UC with no relationship to grade or stage.^{26,27}

Cyclin D1

CCND1 (11q13) is amplified in some superficial and invasive UC,^{57,58} and the protein is overexpressed in an even larger number.^{59,60} Overexpression in many cases may be the consequence of other alterations, such as activation of the MAPK or PI3K pathways (Fig. 64.2A). In Ta tumors, upregulated expression is associated with higher risk of progression to muscle invasion.⁶⁰

KEY MOLECULAR ALTERATIONS IN INVASIVE UROTHELIAL CARCINOMA

Many genomic alterations are found in muscle-invasive (MI) UC, including alterations to known genes and genomic alterations for which the target genes are currently unknown (Table 64.2).

Oncogenes

Overexpression of EGFR, ERBB2, and/or ERBB3 is associated with higher tumor grade and stage and with clinical outcome.^{61–63} *ERBB2* (17q23) is amplified in 10% to 20% and overexpressed in 10% to 50% of MI UC.^{64–66} Amplification is more common in metastatic lesions than in the related primary tumor.⁶⁷ As this receptor cannot bind ligand and relies on heterodimerization with ERBB3, it is likely that ERBB3 status and/or ligand expression may have significant influence.^{65,68,69} Up to 70% of MI tumors overexpress EGFR, and this is associated with poor prognosis.^{61,70,71} Both ERBB2 and EGFR represent potential therapeutic targets in advanced UC.⁷² These changes may activate the RAS-MAPK and/or PI3K pathways (Fig. 64.2A).

RAS gene mutation is not associated with either invasive or noninvasive disease (mutations in ~13% overall).¹⁵ Although mice expressing mutant H-ras in the urothelium develop superficial papillary tumors rather than MI tumors,⁷³ in vitro experiments in human tumor cells indicate that HRAS can induce an invasive phenotype.⁷⁴ Thus, RAS mutation may contribute to development of both major forms of UC.

PIK3CA and *FGFR3* are mutated less frequently than in NMI UC. Approximately 15% of T2 tumors show *FGFR3* mutation.^{3,6,75} However, protein expression is upregulated in 40% to 50% of non-mutant MI UC.⁶ Thus *FGFR3* is considered a good therapeutic target in invasive and metastatic disease and preclinical studies have shown that gene knockdown⁷⁶ or treatment with FGFR-selective small molecules and antibodies inhibits cell proliferation and tumorigenicity of UC cell lines with mutant or upregulated *FGFR3*.^{77–79} Potential predictive biomarkers include mutation, overexpression, or detection of an *FGFR3* fusion protein. The presence of *FGFR3* fusion proteins in UC cell lines¹⁰ is associated with good response to FGFR inhibitors.⁷⁷ Epithelial phenotype may provide an additional biomarker as in vitro assays indicate that

TABLE 64.2

^a Array-based comparative genomic hybridization analyses. HD, homozygous deletion; LOH, loss of heterozygosity.

UC cells with epithelial phenotype have enhanced sensitivity to FGFR inhibition compared to those with mesenchymal phenotype.⁸⁰ A recent RNAi screen in UC cell lines indicated that up-regulated EGFR signaling provides a mechanism of escape from FGFR inhibition and can mediate de novo resistance. A reciprocal relationship was found when EGFR was inhibited and both in vitro and in a preclinical in vivo model, combined inhibition showed improved anti-tumor activity.⁸¹ Thus, assessment of both FGFR3 and EGFR status may be required to predict response and combined EGFR and FGFR3 inhibition may be essential. Several clinical trials of FGFR inhibitors are now planned or in progress in advanced UC.

FGFR1 is also overexpressed in many of these cancers.²³ An increased ratio of the FGFR1- β :FGFR1- α splice variants is found in MI tumors. The β isoform, lacking the first immunoglobulin-like

domain, has increased sensitivity to FGF1.⁸² FGF2 stimulation of ectopically expressed FGFR1- β in some UC-derived cell lines induces an epithelial-mesenchymal transition (EMT), a major feature of which is PLC γ -mediated upregulation of COX-2.⁸³ This is in contrast to the effect of FGFR1 signaling in NHUC, where increased proliferation and reduced apoptosis but no EMT is induced,²³ suggesting that FGFR1 plays different roles in NMI and MI UC. Compatible with this, UC cell lines with highest FGFR1 expression show a mesenchymal (EMT) phenotype (low E-cadherin expression) and upregulated FGF2 expression, and those with epithelial phenotype show higher FGFR3 and E-cadherin and lower FGFR1.⁸⁴ In an animal model of UC metastasis using an FGFR1-dependent cell line, an FGFR inhibitor reduced the development of circulating tumor cells and metastasis but not primary tumor growth.⁸⁴ Currently, there is no information on the

prognostic significance of FGFR1 upregulation, and FGFR1 has not yet been examined independently of FGFR3 as a potential therapeutic target.

Several other oncogenes are implicated in MI UC. Four to six percent have amplification of *MDM2* (12q14).^{57,85,86} *MDM2* regulates p53 levels, and overexpression provides an alternative mechanism to inactivate p53 function (Fig. 64.3). There is no consensus on the relationship of upregulated *MDM2* to tumor grade, stage, or prognosis. *MYC* is upregulated in many bladder tumors, although the mechanism for this is unclear.⁸⁷ Although amplifications of 8q are found in invasive UC, *MYC* is not the major target. However, additional copies of the whole of 8q are common and may lead to overexpression.^{24,57} *MYC* is also upregulated in response to other molecular events (e.g., MAPK pathway stimulation). An amplicon on 6p in 14% of MI UC and cell lines contains *E2F3*, and functional studies indicate that *E2F3* can drive urothelial cell proliferation.^{88–92} *E2F* transcription factors interact with and are regulated by *RB1* (Fig. 64.3) and in accord with this, tumors with *E2F3* amplification have *RB1* or p16 inactivated.⁸⁹

Tumor Suppressor Genes

As in other aggressive cancers, the tumor suppressor genes *TP53*, *RB1*, *CDKN2A*, and *PTEN* are implicated in MI UC. The pathways controlled by *TP53* and *RB1* regulate cell-cycle progression and responses to stress (Fig. 64.3). *TP53* mutation is common in invasive UC and detection of mutation or *TP53* protein accumulation is associated with poor prognosis. Although immunohistochemical detection of *TP53* protein with increased half-life identifies many mutant *TP53* proteins and is commonly used as a surrogate marker for mutation, some *TP53* mutations (~20%) yield unstable or truncated proteins that cannot be detected in this way. Thus, *TP53* protein accumulation is not a useful prognostic marker. Two meta-analyses indicate only a small association between *TP53* positivity and poor prognosis.^{93,94} However, examination of both protein expression and mutation of *TP53* provides useful prognostic information.⁹⁵

The *RB* pathway regulates cell-cycle progression from G1 to S phase (Fig. 64.3). HD, LOH of 13q14, and loss of *RB1* protein expression are common in MI UC.^{96–99} Loss of p16 expression is inversely related to positive *RB1* expression,¹⁰⁰ and high-level p16 expression results from negative feedback in tumors with loss of *RB1*.¹⁰¹ Thus, both loss of expression and high-level expression of p16 are associated with *RB* pathway deregulation, and these are adverse prognostic biomarkers found in >50% of MI tumors.¹⁰² Interestingly, in MI UC with *FGFR3* mutation, a high frequency of *CDKN2A* HD has been reported, which may identify a progression pathway for NMI *FGFR3*-mutant tumors to muscle invasion via loss of *CDKN2A*.¹⁰³ As indicated previously, amplification and overexpression of *E2F3*, which is normally repressed by *RB1*, is associated with *RB1* or p16 loss in MI tumors.⁸⁹ p16 and p14^{ARF} proteins link the *RB* and p53 pathways (Fig. 64.3), and due to multiple regulatory feedback mechanisms, inactivation of both pathways together is predicted to have greater impact than inactivation of either pathway alone. This is borne out by the achievement of greater predictive power in studies using concurrent analyses of multiple changes that deregulate the G1 checkpoint.^{102,104,105}

Altered *PTEN* expression is the most frequent mechanism for deregulation of the PI3K pathway in MI UC. *PTEN* (phosphatase and tensin homolog deleted on chromosome 10) (10q23) is a lipid and protein phosphatase whose major lipid substrate is phosphatidylinositol (3,4,5)-triphosphate (PIP3) generated by PI3K (Fig. 64.2A). *PTEN* LOH is found in 24% to 58% of invasive UC,^{106–108} and copy number analysis has identified a relationship of *PTEN* loss to metastatic disease.⁵⁷ Mutation of the retained copy is infrequent but HD has been detected in tumor cell lines.^{26,109–111} Overall, 46% of UC lines (largely derived from MI tumors) had *PTEN* alterations.²⁶ Reduced expression is common

in tumors^{26,112} and is associated with *TP53* alteration. Many tumors (41%) with altered *TP53* show downregulation of *PTEN*, and this combined alteration is associated with poor outcome.¹¹³ As *PTEN* is haploinsufficient in mouse models,¹¹⁴ loss of one allele in UC may lead to altered phenotype. In mice, conditional deletion of *Pten* in the urothelium led to early urothelial hyperplasia^{112,115} and late development of tumors resembling human papillary superficial tumors. A study that induced stochastic deletion of *p53* and/or *Pten* showed that deletion of either gene alone did not lead to tumor formation, but dual deletion led to early development of aggressive UC, with frequent metastases.¹¹³ *PTEN* loss may affect proliferation, apoptosis, and migration. Reexpression in *PTEN*-null UC cells has revealed effects on cell chemotaxis, anchorage-independent growth, and tumor growth in vivo.^{116–118} UC cell invasion can be inhibited by the protein phosphatase activity of *PTEN* alone.¹¹⁶ Thus, loss of lipid and protein phosphatase activities of *PTEN* may contribute in different ways to urothelial tumorigenesis.

The *TSC1* product hamartin acts in the PI3K pathway downstream of *PTEN* (Fig. 64.2A), providing an alternative mechanism of pathway activation in 13% of invasive UCs that have mutational inactivation.^{26,27} Whereas good response to mTOR inhibitors has been reported in some patients and UC cell lines with mutant *TSC1*, mutation alone is not a sufficient predictive biomarker.^{119,120}

The Rho GDP dissociation inhibitor RhoGDI2 has been implicated as a tumor suppressor in UC. Expression is reduced in an isogenic cell line model of metastasis and low expression is associated with reduced survival in patients with UC.¹²¹ Potential downstream effectors of RhoGDI2 are endothelin and versican, which are upregulated upon loss of RhoGDI2 expression. In an experimental model of metastasis, endothelin 1 was required for lung colonization by UC cells and pharmacologic inhibition of the endothelin axis reduced colonization.¹²² RhoGDI2-regulated versican levels are implicated in enhancing macrophage recruitment and chemokine CCL1 levels.¹²³ As both of these proteins enhance the inflammatory response, the major role of RhoGDI2 may be to inhibit this. RhoGDI2 is phosphorylated by SRC, and this enhances its membrane localization and metastasis-suppression activity.¹²⁴ Compatible with this, and unlike the situation in many tumors, SRC levels in UC are highest in NMI tumors where RhoGDI2 function is intact.^{125,126} SRC contributes to suppression of metastasis via regulation of p190Rho GAP, which in turn downregulates the activity of RHOA, RHOC, and ROCK.¹²⁷

The WNT signaling pathway is also implicated in UC. Mutations in *APC* have been reported,^{27,128} mainly in MI tumors. The frequency of mutations in *CTNNB1* is low, but altered beta-catenin expression (reduced expression or increased nuclear localization) is frequent in MI UC,^{128–131} though this is not associated with *APC* mutation.¹²⁸ Other alterations in the WNT pathway include epigenetic silencing of the antagonists of WNT signaling, secreted frizzled receptor proteins,¹³² and the Wnt inhibitory factor 1 (*WIF1*).¹³³

Other Genomic Alterations in Invasive Urothelial Carcinoma

Invasive UC is often genomically unstable, with significant genetic divergence of related tumors in the same patient over time. Array-based comparative genomic hybridization and single nucleotide polymorphism array analyses have identified many copy number alterations^{57,134–137} (Table 64.2). These include numerous losses and gains in DNA copy number and many regions of high-level amplification that may contain novel oncogenes. To date, the target genes within many of these regions have not been identified. Many regions of copy number alteration show significant association with high tumor grade, stage, and/or outcome. These include amplicons at 1q21–24, 3p25, 6p22, 8p11, 8q22, 11q12, 12q15, and 17q12. Plausible candidate oncogenes within these are *PPARG* (3p25), *E2F3* and *SOX4* (6p22), *FGFR1*, *TACC1* and *POLB* (8p11), *YWHAZ* (8q22),

CCND1 (11q12), *MDM2* (12q15), and *ERBB2* (17q12).^{57,135,138,139} On 1q21–24, at least three regions have been defined, two of which contain plausible candidates (*BCL9* and *CHDIL* in one, and *MCL1*, *SETDB1*, and *HIF1B* in a second).¹³⁹ Regions of HD include 1p34, 2q36, 9p21, 11p11, 18p11, and 19q13.³⁷ On 9p22, *CDKN2A* is one target and two further regions of HD have been identified.⁵⁷ Candidates within the other regions are less obvious.

It is notable that some stage T1 tumors show similar profiles to MI tumors (T2 or greater), suggesting that these tumors with the ability to break through the basement membrane may be aggressive lesions. However, other T1 tumors show remarkable similarity in their copy number profiles to Ta tumors, suggesting that distinct biologic subgroups exist.⁵⁷

INFORMATION FROM EXOME SEQUENCING

At the time of writing, three studies have reported sequencing of whole UC exomes.^{31,32,140} In total, these have sequenced 12 Ta, 41 T1, and 72 T2 tumors. In two studies, selected genes were assessed in larger sample sets to examine prevalence.^{31,140} Whereas the overall numbers of tumors studied remains relatively small, several important conclusions can be drawn. The first is that UC contains a relatively high frequency of somatic single nucleotide mutations, with estimates ranging from 50 to 170 per sample on average but with wide variability between samples. Many of the mutations ($\geq 30\%$) were nonsynonymous, a large proportion of which are predicted to be damaging ($\sim 60\%$ estimated in one study³¹). To date, significant differences in mutation rates between non-aggressive and aggressive tumors are not apparent, though it is notable that very few stage Ta tumors have been studied so far. The most common base change reported is C:G>T:A transition followed by C:G>G:A transversion.

The most significant finding is that in addition to genes already implicated in UC (*TP53*, *FGFR3*, *HRAS*, *KRAS*, *PIK3CA*, *RB1*, *TSC1*), a large number of genes involved in chromatin modification show mutation. In the largest study, 58% of tumors had mutation in chromatin remodeling genes,³² indicating that altered regulation of chromatin is a major oncogenic driver in UC. Mutated genes include histone demethylases (*KDM6A*, *KDM5A*, *KDM5B*, *UTY*), chromatin remodeling genes (*ARID1A*, *ARID4A*), histone lysine methyltransferases (*MLL*, *MLL2*, *MLL3*, *MLL5*), histone acetyltransferases (*CREBBP*, *EP300*, *EP400*), and SWI/SNF complex-related genes (*SMARCA4*, *SMARCA1*). Many of the mutations are predicted to impair function, suggesting tumor suppressor roles. Mutations were also found in DNA repair genes including *ATM*, *FANCA*, and *ERCC2*. Overall, in MI tumors the most frequently mutated genes were *KDM6A* (30%), *TP53* (24%), *ARID1A* (15%), *CREBBP* (15%), *EP300* (13%), *HRAS* (13%), *RB1* (13%), *PIK3CA* (12%), *STAG2* (11%), and *FGFR3* (11%).³² In all three studies, relatively large numbers of genes were mutated at low frequency, suggesting that there is considerable biologic heterogeneity.

EPIGENETIC ALTERATIONS

Epigenetic alterations, mainly those involving DNA methylation, have been widely reported. Most studies have analyzed single genes or small series of genes.^{141–144} Genome-wide analyses have identified novel candidates, some with clinicopathologic associations.^{145–149} In general, hypermethylation in CpG islands is more common in MI tumors and hypomethylation in regions distinct from CpG islands in NMI tumors.^{147,148} Integrated analysis of methylation and gene expression indicates that CpG island hypermethylation is associated with loss of expression and CpG methylation within genes or at transcription factor binding sites with increased expression.¹⁴⁹ Hypermethylation-associated disease progression biomarkers in NMI tumors include *TBX2*, *TBX3*, *TBX4*, *GATA2*, and *ZIC2*.^{145,147} These genes, which encode transcription factors

involved in lineage decisions during development, are implicated in EMT, stem cell phenotype, and differentiation. In the high-risk group of T1 grade 3 tumors treated with BCG, combined methylation of *MSH6* and *THBS1* is associated with disease progression.¹⁵⁰ Hypermethylation of several miRNAs is associated with tumor grade and stage. Some of these have prognostic value (e.g., the miR-200 family and miR-205) and are frequently silenced in MI tumors, and this is correlated with disease progression in T1 tumors.¹⁵¹

There are many reports of improved detection of UC by analysis of methylation biomarkers in urine. Examples include a panel of five biomarkers (*MYO3A*, *CA10*, *NKX6-2*, *DBC1*, and *SOX11* or *PENK*),¹⁵² two panels each of four biomarkers (*ZNF154*, *POU4F2*, *HOXA9*, and *EOMES*),¹⁴⁷ (*APC*, 2 *TERT* CpGs, and *EDNRB*),¹⁵³ one of two markers (*TWIST1* and *NID2*),¹⁵⁴ and one of three markers (*OTX1*, *ONECUT*, and *OSR1*), used in combination with *FGFR3* mutation.¹⁵⁵

To date, chromatin modification has not been extensively studied. In UC cell lines, the active histone mark H3K9Ac and the repressive mark H3K27me3 are associated with miR-200/miR-205 expression or methylation, respectively.¹⁵¹ Genomewide analysis has identified UC-specific differences in the distribution of histone marks and indicated the importance of both DNA and H3K27 methylation in gene silencing in cell lines.¹⁵⁶ In tumor tissues, seven genomic regions where transcriptional deregulation is independent of DNA copy number¹⁵⁷ were shown to be silenced by a mechanism associated with histone H3K9 and H3K27 trimethylation and histone H3K9 hypoacetylation, a pattern of silencing also found in a subgroup of UC with a carcinoma in situ (CIS)-associated expression signature.¹⁵⁸ With the recent identification of many mutations in chromatin remodeling genes in UC,^{31,32,140} more extensive analysis of chromatin modifications and assessment of potential therapeutic opportunities are now needed.

INFORMATION FROM EXPRESSION PROFILING

mRNA expression signatures associated with UC grade, stage, progression, nodal involvement, response to chemotherapy, and survival have been derived,^{134,159–171} and some signatures have performed well in independent validation studies.^{172,173} Overlap between signatures from different studies is generally low, but there is significant overlap in the cellular processes implicated.¹⁷⁴ Clinical application of these signatures requires the development of robust polymerase chain reaction–based assays or identification of antibodies suitable for immunohistochemistry. Already polymerase chain reaction–based gene signatures have been derived to predict progression in NMI tumors.^{169,175} Recently, a novel system of classification for UC based on global analysis of expression data has been developed, and this is discussed in detail in a following section.

There are several reports of altered miRNA expression in UC.^{176,177} Changes in apparently “normal” urothelium from patients with UC indicate that such alterations may occur early in disease development.⁷ Global analyses using array-based methods or deep sequencing have revealed common upregulation of miRNAs in MI tumors and downregulation in NMI tumors.^{7,178} Clustering analysis of miRNA data generated three clusters containing mainly Ta, T1, and T2–T4 tumors.¹⁷⁹ miRNAs downregulated in Ta tumors include miRs 7, 99a/100, 125b, 143, 146, 188, and 29c.^{176,179,180} Many miRNA alterations are found in MI UC.^{151,176,178–183} Examples include upregulation of miR-21,^{7,182} which negatively regulates TP53,⁷ and the miR-200 family, which are implicated in regulation of EMT.¹⁸⁴ Several miRNAs that are downregulated in MI UC (e.g., miR-145, miR-143, miR-203, miR-1, miR-133a, miR-195, and miR-125b) can induce apoptosis, reduce cell proliferation or migration in cultured UC cells, and show reciprocal expression with their targets in tumor tissues.^{185–191} Upregulated miRNAs include miR-222 and miR-452, which are associated with adverse outcome.¹⁹² Downregulation of miR-138 was shown to increase cisplatin sensitivity in UC

cell lines.¹⁹³ Together, these data indicate that miRNA expression profiles may be valuable prognostic biomarkers.

UROTHELIAL TUMOR-INITIATING CELLS

There is evidence for the existence of highly tumorigenic subpopulations of cells with stem cell–like characteristics within UC populations. As cancer stem cells in other tumor types show resistance to chemotherapy agents and are predicted to be the cause of posttreatment disease relapse, there is great interest in characterizing these cells and identifying markers that may allow specific targeting. Isolation of bladder cancer “stem” or “tumor-initiating” cells has been attempted from fresh tumor tissues and UC cell lines, using a range of assays. The putative stem cells express a range of markers including 67kD laminin receptor (67LR), CD44, CD90, ALDH1A1, and keratins 5, 14, and 17.^{194,195} The majority of these are markers expressed by normal urothelial basal cells and in low-grade tumors, cells expressing these markers reside at the tumor-stromal interface.¹⁹⁶ Cell surface markers have been used to great effect to sort putative stem cells from mass cell populations. Cells from tumor samples that expressed CD44+, CK5+, CK20– had enhanced tumor-initiating ability compared to CD44–, CK5–, CK20+ cells and could generate tumors that contained both CD44+ and CD44– cells.¹⁹⁷ In UC cell lines, a subpopulation of CD44+, ALDH1A1+ cells is reported to have higher tumorigenicity than CD44–, ALDH1A1– cells, and in UC tissues higher ALDH1A1 expression was an independent prognostic factor for overall survival.¹⁹⁸ However, the finding that 58% of UC do not express CD44¹⁹⁷ has suggested that not all UC stem cells are derived from the basal compartment. Combinations of markers related to different urothelial differentiation states were found to stratify UC into clinically relevant subgroups; in each group, it was found that the least differentiated cell type showed stem cell–like characteristics.¹⁹⁹ This implies that UC stem cells can be derived from urothelial cells of different differentiation states. This diversity in stem cell phenotype may influence subsequent disease development and may have prognostic value.

MOLECULAR PATHOGENESIS AND TUMOR CLONALITY

Multifocality and/or development of multiple recurrent tumors in the same patient is a common feature of UC. Although some patients develop more than one molecularly distinct tumor (oligoclonal disease),²⁰⁰ most commonly tumors from the same patient are molecularly related,^{201–203} with evidence for subclonal genomic evolution in different lesions.²⁰⁴ Chromosome 9 LOH has been proposed as an early event in UC development as it is found in “normal” urothelium and hyperplasia in tumor-bearing patients.^{205,206} Compatible with this, loss of the same allele is commonly shared by all related tumors.²⁰⁷ Construction of phylogenetic trees from multiple related NMI tumors confirms the early loss of chromosome 9 with later events including 11p–, 20q+, 17p–, and 11q–.²⁰³ Interestingly, tumors with highest genomic complexity are not necessarily the last to appear in the patient.^{208,209}

Urothelial dysplasia and CIS, predicted precursors of MI UC, show frequent chromosome 9 LOH and TP53 mutation,^{210–212} and multiple other chromosomal alterations.²¹³ Detailed genomic mapping of cystectomy specimens has indicated that prior to detectable morphologic abnormality, large areas of urothelium show LOH of specific chromosomal regions. Areas of dysplasia showed more complex patterns of LOH, suggesting sequential evolutionary changes associated with acquisition of growth advantage. Thus, it is suggested that development of MI UC involves displacement of the normal urothelium by a molecularly altered clone, within which subclones with additional alterations arise. Six critical regions of LOH (3q22, 5q22–23, 9q21, 10q26, and 17p13) were identified.^{214,215} Biallelic inactivation of *ITM2B* and *P2RY5*, genes close to *RBI*, implicate these in driving early clonal expansion.²¹⁴

Polyclonal hypermethylation detected throughout the “normal” urothelium in tumor-bearing bladders also suggests widespread pre-malignant epigenetic “field change.”¹⁴⁸ The genes affected, which may represent early “drivers” of UC, include *ZO2*, *MYOD1*, *CDH13*, and many polycomb repressive complex 2 (PRC2) targets, all of which have plausible functional significance and showed hypermethylation in the related invasive tumors.

MULTIPLE TUMOR SUBGROUPS DEFINED BY MOLECULAR PROFILING

Bladder tumors of similar grade and stage commonly show divergent clinical behavior. In particular, stage T1 tumors show considerable molecular and clinical diversity. Until recently, molecular features have failed to explain or predict this heterogeneity. The two tumor groupings that have for so long dominated the bladder cancer literature are insufficient for this. Recent studies have begun to unravel this complexity, revealing multiple subgroups that are independent of conventional grade and stage groupings (Fig. 64.4).

Initial assessment of mRNA expression profiles of UC of all grades and stages identified the two major molecular subtypes, separated mainly though not entirely, according to grade and stage with stage T1 tumors distributed relatively equally between the two.^{134,135} More recent analysis has defined additional subtypes. Five major subtypes were termed urobasal A (UroA), UroB, GU, squamous cell carcinoma–like (SCCL), and “infiltrated”²¹⁶ (Fig. 64.4A). Tumors in the latter group are highly infiltrated with nontumor cells, whereas the definition of the other groups reflects tumor cell–specific criteria. Clear differences in expression of cell cycle regulators, keratins, receptor tyrosine kinases, and cell adhesion molecules are evident. UroA and UroB subtypes express high levels of *FGFR3*, *CCND1*, and *TP63*; GU tumors show low levels of these proteins but high levels of *ERBB2* and *E-cadherin*; and SCCL tumors express *P-cadherin* and high levels of *KRT5*, *KRT14*, and proteins involved in keratinization. These subtypes showed distinct clinical outcome. UroA had good prognosis, GU had intermediate prognosis, and SCCL and UroB, the worst prognosis. UroB tumors share epithelial characteristics with UroA tumors including *FGFR3* mutation, but they also show *TP53* mutation and are often invasive. T1 tumors appear evenly distributed between molecular subtypes.²¹⁶

Robust assays, ideally based on immunohistochemical detection of proteins in formalin-fixed, paraffin-embedded tissues are required to apply these findings in the clinic. Immunohistochemistry of a panel of markers selected from the defined mRNA subgroup signatures has recently been assessed in combination with morphologic criteria.²¹⁷ Histopathologic and immunohistochemical profiles were examined in all subtypes except “infiltrated,” with excellent correlation between mRNA and protein expression for the majority of markers. Importantly, the distribution of protein expression within the tissues also provided valuable information. For example, UroA tumors show restriction of *KRT5*, *P-cadherin*, *EGFR*, and *CCNB1* expression to the basal cell layer, reminiscent of normal urothelium, implying retention of dependence on stromal interactions, whereas many UroB tumor show expression of these proteins in suprabasal layers. The keratin expression profile (*KRT14+*, *KRT5+*, *KRT20–*) of SCCL tumors is characteristic of the least differentiated class of tumor initiating cells described by Chan et al.¹⁹⁷ and termed “basal” in the study of Volkmer et al.¹⁹⁹ Their phenotype is also similar to basal-like breast carcinoma,²¹⁸ and it has been suggested that these UC could in future be defined as “basal-like.”²¹⁷

A simple classifier based on grade and urothelial differentiation pattern and expression of *KRT5* and *CCNB1* was able to reproduce the original genomewide expression classification with an accuracy of 0.88.²¹⁷ The three major subgroups, urobasal (UroA + UroB), GU, and SCCL, showed highly significant association with disease-specific survival. However, a simple method to distinguish UroA from the small, related UroB subset, many of which are MI, proved difficult.²¹⁷ The common features of UroA and UroB may indicate that MI UroB tumors have their origins as non-invasive

Figure 64.4 Tumor subgroups defined by molecular profiling. **(A)** Major bladder cancer subtypes identified by mRNA expression profiling (adapted with permission from Sjobahl et al.²¹⁶). Hierarchical cluster analysis of 308 samples generated five major tumor clusters. Each column of the heatmap represents one sample, and each row represents one gene. *Green* represents low gene expression, and *red* represents high gene expression. The five major subtypes are indicated by the *color bars* at the top of figure. GU, genomically unstable; SCCL, squamous cell carcinoma-like; UroA, urobasal A; UroB, urobasal B; Infil, "infiltrated". **(B)** Major bladder cancer subtypes identified by array-based comparative genomic hybridization.⁵⁷ Hierarchical cluster analysis was performed using copy number data from 160 tumors. *Red* represents copy number loss, and *green* represents copy number gain. Chromosome number is shown down the right-hand side of the figure. Eight main clusters of tumors were identified, and these are indicated by the *color bars* at the top of the figure.

UroA tumors. Interestingly, UroB showed common loss of p16 expression, which as discussed previously, may represent a means by which NMI *FGFR3*-mutant tumors can progress.¹⁰³ In common with NMI tumors, UroB retains TP63 expression and may represent the aggressive subset of TP63-expressing advanced UC reported by Choi et al.²¹⁹ Further studies of this subtype are essential to allow development of a clinically applicable classification assay.

Similarly, DNA copy number and mutation status has identified multiple subgroups of tumors within the conventional grade and stage groupings⁵⁷ (Fig 64.4B), though these have not been as extensively studied as expression-based subtypes and classification signatures are not yet defined. DNA methylation profiles also identify several subtypes.^{148,149,220} Four "epitypes" showed broad alignment with expression subtypes.¹⁴⁹ One epitype showed methylation pattern similar to immune cells and represented the heavily infiltrated group of tumors. Two others corresponded to the two major expression subtypes,^{134,135} one of which contained many aggressive

tumors with upregulation of *EZH2* and corresponding DNA methylation of polycomb target genes and several *HOX* genes, whose hypermethylation is implicated in aggressive growth of other cancer types. As for expression subtypes, these epitypes do not align absolutely with tumor grade and stage. Integration of information from all genome-wide platforms, including miRNA expression data, is now needed to provide optimum prognostic and predictive biomarkers. As DNA and miRNA are more robust molecules than RNA in formalin-fixed, paraffin-embedded specimens, a combination of these and protein biomarkers may ultimately be most useful.

ACKNOWLEDGEMENTS

We acknowledge the valuable advice of Professor M Höglund and Dr KS Chan on the sections on tumor subgroups and urothelial tumor-initiating cells.

65 Cancer of the Bladder, Ureter, and Renal Pelvis

Adam S. Feldman, Jason A. Efstathiou, Richard J. Lee, Douglas M. Dahl, M. Dror Michaelson, and Anthony L. Zietman

INTRODUCTION

This chapter details the incidence, epidemiology, pathology, and treatment of cancers of the bladder, ureter, and renal pelvis. Transitional cell carcinomas (TCC) constitute 90% to 95% of all the urothelial tumors diagnosed in North America and Europe. TCCs occur throughout the lining of the urinary tract from the renal calyceal system to the proximal two-thirds of the urethra, at which point squamous epithelium predominates. In this 10th edition, cancers of the renal pelvis and ureter are grouped with bladder cancer rather than with cancers of the kidney. This is a natural fit, because approximately 90% of the urothelial cancers of the renal pelvis, ureter, and bladder are transitional cell cancers, all of which share similarities in epidemiology, pathology, biology, patterns of spread, molecular tumor markers, and treatment. The chapter presents the common characteristics of urothelial cancers in an initial section and then deals in subsequent sections with the separate characteristics of these organs. The multidisciplinary treatment of this chapter reflects the current approach to patients with these diseases.

UROTHELIAL CANCERS

Epidemiology

Bladder cancer is almost three times more common in males than in females and more common in whites than in blacks. In 2013, there were approximately 72,570 new cases in the United States, over a 20% increase from 20 years ago. The incidence increases with age and peaks in the 6th, 7th, and 8th decades of life.¹

Simultaneous or subsequent development of TCC of the urethra in patients with TCC of the bladder occurs with an incidence of 6% to 16% more commonly in women than men and in those with recurrent multifocal bladder cancers, and bladder neck or trigonal involvement with either invasive cancer or carcinoma in situ (CIS).^{2,3}

The incidence of ureteral TCC is 0.7 per 100,000, whereas renal pelvic TCCs have an incidence of 1 per 100,000.⁴ Renal pelvic tumors constitute 5% of all renal tumors, and 90% of them are TCCs. Squamous cell carcinoma and adenocarcinoma constitute the majority of the remainder. Renal pelvic transitional cell cancers constitute 5% of all TCCs of the urinary tract. Patients who have primary TCCs of the renal pelvis or ureter have a 20% to 40% incidence of either synchronous or metachronous bladder cancer. Conversely, patients with bladder cancer have a 1% to 4% incidence of synchronous or metachronous upper tract urothelial tumors.^{5,6} However, if the bladder cancer is grade 3, there is associated CIS, or the patient has failed intravesical chemotherapy, some reports suggest a doubling of the incidence of upper tract tumors.⁷ Patients with Balkan nephropathy have an increased incidence of upper tract tumors; these tumors are usually low grade and multiple.⁸

Recently, aristolochic acid, a component of all *Aristolochia* plants, was identified as the etiologic agent causing Balkan nephropathy and the associated urothelial carcinoma.^{9–11} In the Balkan region, the exposure seems to occur via consumption of bread made from flour contaminated with *Aristolochia clematitis* seeds.¹² There are also specific areas of Taiwan where TCC of the renal pelvis accounts for 40% of all renal tumors, whereas in other nonendemic areas, the upper tract tumors account for only 1% or 2% of renal tumors.¹³ Aristolochic acid has also recently been identified as the etiology in this population due to widespread use of *Aristolochia* herbal remedies.^{14,15}

Risk factors for urothelial cancer may be classified into one of three categories: (1) gene abnormalities that result in perturbations in cell cycle regulatory processes, (2) chemical exposure, or (3) chronic irritation. Those risk factors that involve genetic abnormalities include chromosome deletions or duplications, proto-oncogene expression, tumor suppressor gene mutation, and abnormalities of specific cell cycle regulatory proteins. In non-muscularis propria-invasive transitional cell cancers, deletions of part or all of chromosome 9 and alterations in the gene encoding for fibroblast growth factor receptor 3 (FGFR3) are often encountered. Inactivation of the cohesion subunit stromal antigen 2 (Stage 2), which regulates sister chromatid cohesion and segregation, is frequently found in low-grade and low-stage bladder cancer.^{16–18} Other proto-oncogenes that have been implicated in bladder cancer include the RAS and p21 proteins.¹⁹ Genetic abnormalities associated with CIS include alterations in the retinoblastoma gene (Rb), p53, and phosphatase and tensin homolog (PTEN). In muscularis propria-invasive disease, the tumor suppressor genes that have been associated with an altered biology and more aggressive behavior include the p53 and the Rb gene.²⁰ Abnormalities in specific cell-cycle regulatory proteins such as epidermal growth factor (EGF), Ki-67, cyclin D1, metalloproteinase (MMP), and tissue inhibition of metalloproteinase (TIMP) have also been implicated.^{20–25} At this time, there is no single molecular marker that is capable of predicting the tumor with a high degree of accuracy, which may result in muscularis propria invasion or distant metastases.

Chemical exposure has perhaps the most epidemiologic evidence to support it as an inciting agent. Aromatic amines, aniline dyes, and nitrites and nitrates have all been implicated. There are genetic polymorphisms that appear to increase the susceptibility of affected patients exposed to carcinogens. *N*-acetyltransferase, which detoxifies nitrosamines and glutathione-S transferase, which conjugates reactive chemicals, have been implicated in increasing the risk for the development of bladder cancer in patients so afflicted. Tobacco use carries with it, for those who continue to smoke, a threefold increased risk of developing bladder cancer, and even ex-smokers have a twofold increased risk.²⁶ Numerous reports have shown strong associations between the development of both bladder and upper tract TCCs with industrial contact to chemicals, plastics, coal, tar, and asphalt, and aristolochic acid, as discussed previously. Cyclophosphamide administration over the

long term, particularly in patients who have upper tract or bladder outlet obstructions, results in an increased risk of bladder cancer. These cancers, when discovered, tend to be particularly aggressive. Coffee, tea, analgesics, alcohol, and artificial sweeteners have not been shown to act as independent risk factors.

Chronic irritants include catheters, recurrent urinary tract infections, *Schistosoma haematobium*, and irradiation. Chronic irritation due to indwelling catheters associated with chronic infection increases the risk for the development of squamous cell carcinoma; a *S. haematobium* infestation results in an increased risk of squamous cell and TCCs; pelvic irradiation also carries with it an increased risk of developing a urothelial cancer.

There are many studies that suggest high water consumption, vitamin intake, and various diets as beneficial in preventing bladder cancer. However, none of these have shown any clear benefit with respect to prevention.

Screening and Early Detection
